The traditional logic and consistency of this system made it very popular in the Soviet Union. It really indicates the essence of soil formation in different zones (in accordance with the central images of types) and allows soil development in a changing environment to be forecast; it uses traditional nomenclature of Russian soils and its influence can be traced in many national classifications. However, this classification was considered by others to be outdated and is considered by some to be inappropriate—given the new knowledge—on the soils of Russia. Moreover, the system embraced only soils of agriculturally suitable areas. Little attention was paid to human-modified soils. Using the basic factor approach, this classification system could not provide distinct morphological diagnostics of soil types and subtypes in these environments. Finally, it was considered to be based on a static understanding of the nature of soils and soil-forming environments and could not accommodate soils that did not fit the subtype criteria; therefore, Siberian and northern soils could not be inserted into the system without considerable changes in its principles and structure. These drawbacks of the official system and the scarcity of appropriate information on the western classification systems provided the impetus for a new search in the field of soil classification in the late 1970s and 1980s.

The categorization of pedogenetic processes initiated by Neustruev in 1922 was further developed by his pupil Gerasimov,^[7] who, sticking to his “factors–processes–properties” triad, actively supported the idea of profile formulae (a similar profile formula approach using horizon sequences was suggested by Fitzpatrick).^[8] Such formulae presented sequences of horizons diagnostic for the majority of soil types. This was a change toward a substantive-genetic ideology in classifying soils.

Fridland^[9] initiated the development of a new composite soil classification system based on three components: 1) regime; 2) petrographic–mineralogical; and 3) profile-genetic component. The latter component presumed the assessment of soil properties via diagnostic horizons, in the definition of above-type categories. It evolved into the new soil classification of 1997.^[10]

Classification of Soils of Russia^[11] is an open, substantive-genetic system, embracing soils of all regions. Soil properties related to genesis are used as criteria for the highest taxonomic categories (Trunks and Orders), and soil types, traditionally being central units of the system, are specified by sequences of diagnostic soil horizons.

These horizons are defined by the integrity of substantive soil properties, whose choice is controlled by pedogenetic processes. Environmental agents, including climatic parameters, are virtually excluded from the diagnostics of most soil taxa. Special attention is paid to human-modified soils. Together with corresponding natural soils, they are perceived as a conceptual or spatial continuum: from natural soils to modified natural-anthropogenic soils and, finally, to non-soil surface formations. The taxonomic position of human-modified soils does not take into account the goals and character of impacts on soil and the level of soil fertility; it is fully dictated by the morphology of soil profile. Traditional soil names were preserved and supplemented by new constructions for human-modified soils and non-soils.

The new Russian system has a number of features in common with the International and American systems in terms of methodology, in particular, in the attitude to soil horizons. However, in spite of many efforts, the correlation of soils between the systems remains broadly inadequate, and this may be a challenge in the future.

Classification Systems: South African

Jeffrey C. Hughes

Soil Science, School of Environmental Sciences, University of KwaZulu-Natal,
Scottsville, South Africa

Abstract

This entry presents the South African classification system. The available soil classification has its roots in a number of important field studies. Concepts and characteristics brought in from other systems include the luvic character of B horizons, the placic pan, and the use of the plasticity index to distinguish between vertic and non-vertic topsoils. However, the system has retained its local character.

INTRODUCTION

The new soil classification has its roots in a number of important field studies, the most influential of which covered 11,000 square miles of the Tugela (Thukela) river basin in KwaZulu-Natal.^[1] Two coauthors of that survey, C.N. MacVicar (later, Director, Natal Region, Department of Agriculture) and J.M. de Villiers (later, Chair of Soil Science at the University of Natal), became two of the most influential figures in soil classification in South Africa. The classification presented in 1969, in the publication *Soils of the Tugela Basin*,^[1] laid the foundation for those who followed.

THE TUGELA BASIN CLASSIFICATION

The soils of the survey area were subdivided into 29 soil forms at the highest level in the classification and into 110 soil series at the most detailed level. Thus, just two levels in the hierarchy were recognized—a feature that has remained in all subsequent changes. The concept of the soil form was “developed to include all soils that have the same kind and number of diagnostic horizons, arranged in the same vertical order.”^[1] The soil series were distinguished from the forms by using soil properties that were either not used to define the forms or, where properties were used, a narrower range of variation was employed at the series level. The major criteria used for defining the soil series were texture, base status, and calcareousness. In individual soil forms, characteristics such as pH and surface crusting were used. The classification also recognized that not all the possible soil series were present within the basin and that there would be others found elsewhere in the country. Gaps were therefore left so that the series could be slotted in as they were identified.

Eighteen diagnostic horizons were defined with their general connotation, i.e., the meaning behind the definition and where they were most likely to be found. All the soil

forms and series were named after the geographic location where the “type” of soil was identified. One of the major features of this classification was its simplicity since almost all the properties needed to classify a soil were identifiable in the field. The main exception to this was base status (dystrophic, mesotrophic, or eutrophic), although this could often be inferred from other characteristics such as the vegetation, climate, and soil structure. Base status, together with other field-estimated or measured properties such as pH and texture, needed confirmation by laboratory measurement to finalize the classification of some soils. The degree of success that this system achieved can be measured by so many of its features having been retained in future editions of the classification.

THE BINOMIAL SYSTEM

Soil Classification—A Binomial System for South Africa

This was the first detailed system that allowed for the classification of the soils of South Africa,^[2] as opposed to individual classifications developed for specific areas of the country. Its publication resulted only after considerable consultations with the major role players in South Africa and extensive in-field testing. The authors also recognized in the preface that “This is the first edition; it is certain that the system as presented here is not the final word.”^[2] The classification in many ways followed the same format as the Tugela Basin survey. The name “binomial” came from the fact that soils were classified into two classes: soil form and soil series. In total, 41 soil forms and 504 soil series were recognized and described. As in the Tugela Basin survey, the soil forms were defined on the basis of a unique vertical sequence of diagnostic horizons. A total of 5 topsoil and 15 subsoil horizons were defined, and, as before, each had a connotation in terms of presumed genesis and provenance. The soil series (and soil forms) had unique

geographic names, and the series were also given a number within their soil form, which in turn had a unique two-letter code. Thus, e.g., the Griffin form, Farmhill series has a notation Gf 13; the Cartref form, Cranbrook series has a notation of Cf 22. This greatly facilitated soil mapping, soil survey, and communication. The main soil series criteria were again texture, base status, and calcareousness, with horizon color (especially the distinction between defined red and non-red colors) and pH important in some soil forms. The format followed that begun in the Tugela survey in that each soil form was represented by a full-color plate and the series criteria were given on the facing page. This classification also included some useful features, notably that each soil form was given possible correlations to the Food and Agriculture Organization (FAO)^[3] and U.S. Department of Agriculture^[4] classifications. Although, of necessity, these were only broadly equivalent, they did introduce the local users of the classification of these two more widely known classifications and, internationally, allowed readers of the binomial system to relate to terminology with which they would be familiar. The system also included a full glossary. Perhaps most importantly, the system retained its user-friendly nature in that it remained possible to classify almost all soils to series level *in the field* (with the same provisos as earlier), without resorting to expensive laboratory analyses. A criticism leveled at the binomial system was that, because it was based on the evidence of previous soil surveys, it contained no differentiae that those surveys had not recognized.^[5] Thus, it lacked the previous flexibility. However, as stated earlier, the authors recognized that it was just “the first edition” and that as knowledge expanded the classification would have to be modified. Perhaps a more important limitation to the binomial system was that it was based strongly on the knowledge built up within the Province of KwaZulu-Natal and drew heavily on the Tugela Basin survey information. This resulted in the (very different) soils of the Cape Province, especially, being largely restricted to two Podzol forms and to the calcareous series of a few of the other soil forms. These restrictions made it inevitable that a second edition would be needed.

Soil Classification—A Taxonomic System for South Africa

The new soil classification^[6] is the second (revised) edition of the binomial system and retains many of the features of that classification although there are some fundamental differences. As stated in the preface, the main pressure for a second edition came from soil scientists in the Cape Province (see above). The major change to the classification itself was the decision to “include only those classes which accommodate similar, naturally occurring, more or less uniform soil bodies (polypedons), and to exclude arbitrarily chosen classes (mainly texture) which cause uniform soil bodies to be split artificially by class boundaries.”^[6]

This reflects a change in philosophy from the Tugela survey where, in explaining the use of the term “soil individual,” the authors stated “The U.S.D.A. Soil Survey Staff has defined discrete individuals of the soil population in terms of three-dimensional bodies of soil (polypedons). We fail to see the necessity, or logic of this.”^[1] The decision to exclude texture as a differentiating criterion, given that it was the major feature that distinguished the soil series in the binomial system, meant that soil series were omitted from the classification, and the lowest level became the soil family. It was also felt that the information needed to define the series satisfactorily was not generally available. By excluding the most detailed level of the classification, the soil series, the authors also tacitly recognized that the criticism leveled at the binomial system by Butler^[5] had some basis. Despite texture being excluded from the new classification, there is a recommendation that the texture of the *topsoil* should be appended to the formal communication of any particular soil. This emphasis on the topsoil texture only makes this classification unusual (unique?) since others generally use the texture of the subsoil as a differentiating feature. The classification thus consists of two levels, namely soil form and soil family. As in the first edition, all form and family names are from geographic locations, and none of the earlier series names is used in the second edition. Similarly, the forms are designated by unique two-letter codes and the families by four-digit numbers, e.g., the Estcourt form, Zastron family is designated Es 1100; the Clovelly form, Brereton family is designated by the code Cv 1200. The number of forms recognized has increased to 73, with a total of 404 soil families. There are 5 diagnostic topsoil horizons and 25 diagnostic subsoil horizons or materials (Fig. 1).

Concepts and characteristics brought in from other systems include the luvisc character of B horizons, the placic pan, and the use of the plasticity index to distinguish between vertic and non-vertic topsoils. However, the system has retained its local character in that the terminology of many diagnostic horizons is different from that used elsewhere. Examples include Podzol B (not spodic), hardpan carbonate horizon (not calcrete), and a particular usage of the term “saprolite.” The classification book also includes the methods of analysis as appendices used for the distinguishing criteria, an outline of the diagnostic horizons from the FAO^[7] and the U.S. Department of Agriculture^[8] soil classifications, and a full glossary. However, lacking from the second edition is any attempt to correlate the South African system with either of these more generally used international systems. The increase in the number of forms is mainly accounted for by the increase in the podzolic soils from 2 in the first edition to 8, the recognition of 19 arid-zone soils [either with calcareous B horizons or underlain by dorbank (a hard subsurface horizon cemented by silica)]—these two categories largely cater for the soils of the Cape Province—and 3 more soils underlain by wet materials. The families are distinguished by a total of

Fig. 1 Diagnostic horizons and materials.

Source: From Courtesy of the Director, Institute for Soil, Climate and Water, Pretoria and Soil Classification Working Group.^[6]

19 characteristics, of which color, base status, calcareousness, luvic character in the B horizon, and signs of wetness in the subsoil are the most important. The classification has retained many of the positive features of the earlier ones remaining one of the most user-friendly classifications, with it being a very large field classification. However, the addition of measurable characteristics such as the plasticity index to distinguish vertic soils and the addition of a cation exchange capacity criterion to distinguish borderline structured from apedal subsoils mean that laboratory data are more necessary now than in the past.

CONCLUSION

Discussions are underway among the South African soil science community with a view to decide on the next edition of the soil classification and what changes are required. The main item of contention is whether we are in a position to define soil series satisfactorily and, if so, what differentiae should be used. The decision not to reuse any of the earlier soil series names in the new classification means that they could be brought back into any future edition, provided that their characteristics can be agreed upon. What is certain is that the new classification will not be the final word as South African soil science develops, and more knowledge is gained about the country's soil mantle.

Clay Minerals

Abstract

Clay minerals refer to a group of hydrous aluminosilicates that predominate the clay-sized ($<2\ \mu\text{m}$) fraction of soils. These minerals are similar in chemical and structural composition to the primary minerals that originate from the earth's crust; however, transformations in the geometric arrangement of atoms and ions within their structures occur due to weathering. Primary minerals form at elevated temperatures and pressures and are usually derived from igneous or metamorphic rocks. Inside the earth, these minerals are relatively stable, but transformations may occur once exposed to the ambient conditions of the earth's surface. Although some of the most resistant primary minerals (quartz, micas, and some feldspars) may persist in soils, other less resistant minerals (pyroxenes, amphiboles, and a host of accessory minerals) are prone to breakdown and weathering, thus forming secondary minerals. The resultant secondary minerals are the culmination of either alteration of the primary mineral structure (incongruent reaction) or neoformation through precipitation or recrystallization of dissolved constituents into a more stable structure (congruent reaction). These secondary minerals are often referred to as phyllosilicates because, as the name implies (Greek: *phyllon*, leaf), they exhibit a platy or flaky habit, while one of their fundamental structural units is an extended sheet of silicate tetrahedra.

STRUCTURE OF CLAY MINERALS

The properties that determine the composition of a mineral are derived from its chemical foundation, geometric arrangement of atoms and ions, and the electrical forces that bind them together.^[1] Given that there are eight elements that constitute over 99% of the earth's crust (Table 1), the inclusion of these in the elemental makeup of soil minerals is understandable. Notwithstanding, the prevalence of silicon and oxygen in the phyllosilicate structure is logical. The SiO_4 tetrahedron is the foundation of all silicate (SiO_4) structures. It consists of four O^{2-} ions at the apices of a regular tetrahedron coordinated to one Si^{4+} at the center (Fig. 1). An interlocking array of these tetrahedral connected at three corners in the same plane by shared oxygen anions forms a hexagonal network called the tetrahedral sheet.^[2] When external ions bond to the tetrahedral sheet, they are coordinated to one hydroxyl and two oxygen anion groups. An aluminum (Al), magnesium, or iron ion typically serves as the coordinating cation and is surrounded by six oxygen atoms or hydroxyl groups resulting in an eight-sided building block termed an octohedron (Fig. 1). The horizontal linkage of multiple octahedra comprises the octahedral sheet. The minerals brucite ($\text{Mg}(\text{OH})_2$) and gibbsite ($\text{Al}(\text{OH})_3$) are similar to the octahedral sheets found in many clay minerals; however, phyllosilicates may contain coordinating anions

other than hydroxyls. Cations in the octahedral layer may exist in a divalent or trivalent state. When the cations are divalent (Mg , Fe^{2+}), the layer exhibits a geometry similar to brucite, such that electrical neutrality is maintained. In this arrangement, the ratio of divalent cations to oxygens is 1:2, and all three possible cation sites in the octahedron are occupied. This configuration and the respective sheet formed from an array of such as octahedral are referred to as trioctahedral. When the cations are trivalent (Al , Fe^{3+}), the charge balance is maintained by leaving one of every three octahedral cation sites empty. Under this configuration, the ratio of trivalent cations to oxygens is 1:3, and the layer exhibits a gibbsite-like dioctahedral arrangement. A combination of tetrahedral and di- or trioctahedral sheets bound by shared oxygen atoms forms aluminosilicate layers that comprise the basic structural units of phyllosilicates (Fig. 2). Sheet arrangement within the aluminosilicate layers varies between clay mineral types, resulting in variable physical and chemical properties that differentiate the clay mineral classes.

ISOMORPHOUS SUBSTITUTION

The structural arrangement of the elements described above forms the template for the SiO_4 clay minerals. However, the composition varies frequently due to substitution of ions

Table 1 Common elements in earth’s crust and ionic radius.

Element	Crustal average (g kg ⁻¹)	Ionic radius (nm)	Volume (%)
O ²⁻	466.0	0.140	89.84
Si ⁴⁺	277.2	0.039	2.37
Al ³⁺	81.3	0.051	1.24
Fe ²⁺	50.0	0.074	0.79
Mg ²⁺	20.9	0.066	0.60
Ca ²⁺	36.3	0.099	1.39
Na ²⁺	28.3	0.097	1.84
K ⁺	25.9	0.133	1.84

within the mineral structure. Weathering allows for the substitution of Si⁴⁺, Al³⁺, and Mg²⁺ with cations with comparable ionic radii in their respective tetrahedral and octahedral sheets (Table 1). Consequently, Si⁴⁺ may be replaced by Al³⁺ in the center of the tetrahedron without changing the basic structure of the crystal. Moreover, cations such as Fe^{3+/2+} and Zn²⁺ (ionic radius = 0.074 nm) may replace Al³⁺ and Mg²⁺ in the octahedra. The process of replacing one structural cation for another of similar size is referred to as isomorphous substitution. This replacement represents the primary source of both negative and positive charges in clay minerals. For example, the substitution of one Al³⁺ for a Si⁴⁺ in the tetrahedron results in a gain of one negative charge.

Alternatively, replacement of a lower valence cation by one with a higher valence (Fe²⁺ by Fe³⁺) results in a gain of one positive charge. Some clay minerals exhibit substitutions that result in both positive and negative charges. A balance of electron loss and gain within the structure determines the net charge of the mineral. In most soils, however,

Fig. 1 The basic structural components of clay minerals: (A) a single four-sided tetrahedron and (B) a single eight-sided octahedron.

Fig. 2 Diagrammatic sketch of a 1:1 clay mineral consisting of one tetrahedral sheet bonded to an octahedral sheet (kaolinite) and a 2:1 clay mineral consisting of an octahedral sheet bound between two tetrahedral sheets (pyrophyllite). Source: From Grim.^[3]

substitutions that result in net negative charge exceed those producing a positive charge.

CLAY MINERAL CLASSIFICATION

Clay minerals are generally classified into three layer types based upon the number and arrangement of tetrahedral and octahedral sheets in their basic structure. These are further separated into five groups that differ with respect to their net charge (Table 2).

1:1 Clay Minerals

The 1:1 layer minerals contain one tetrahedral and one octahedral sheet in their basic structural unit (Fig. 2.) This two-sheet mineral type is represented by the kaolin group, with the general formula Al₂Si₂O₅(OH)₄. Kaolinite, the most common mineral in this group, is dioctahedral, exhibiting Al³⁺ octahedral and Si⁴⁺ tetrahedral coordination. The sheets are held together by van der Waals bonds

Table 2 Properties of clay mineral groups.

Group	Layer type	Net negative charge (cmol kg ⁻¹)	Surface area (m ² g ⁻¹)	Basal spacing (nm)
Kaolinite	1:1	2–5	10–30	0.7
Fine-grained mica	2:1	15–40	70–100	1.0
Smectite	2:1	80–120	600–800	1.0–2.0
Vermiculite	2:1	100–180	550–700	1.0–1.5
Chlorite	2:1:1	15–40	70–100	1.4

Source: Adapted from Brady.^[4] ©1990 Macmillan Publishing Co.

between the basal oxygens of the tetrahedral sheet and the hydroxyls of the octahedral sheet. Layers are held together tightly by hydrogen bonding, which restricts expansion and limits the reactive area to external surfaces. Isomorphic substitution for Si⁴⁺ and Al³⁺ in this mineral is negligible. As such, soils dominated by 1:1 minerals exhibit a low capacity for adsorbing cations and have low fertility. The serpentine group, with the general formula Mg₃Si₂O₅(OH)₄, represents the trioctahedral version of the 1:1 layer minerals.

2:1 Clay Minerals

The joining of two tetrahedral sheets (one from each side) to one octahedral sheet produces a three-sheet mineral type, which is called 2:1 and is represented by the mica, smectite, and vermiculite groups. Talc [Mg₃Si₄O₁₀(OH)₂] and pyrophyllite [Al₂Si₄O₁₀(OH)₂] are typical representatives of electrically neutral 2:1 type minerals in which adjacent layers are joined to each other by van der Waals bonds (Fig. 2). Although these two minerals are found infrequently in soils,^[2] their structure serves as a model for discussing transitions leading to the formation of other more common 2:1 clay minerals.

The true micas have a similar structure to that of talc and pyrophyllite, except that substitution of Al³⁺ for Si⁴⁺ in every fourth tetrahedral site results in an excess of one negative charge per formula unit. The negative charge is satisfied by monovalent cations, primarily K⁺, that reside on interlayer sites between the 2:1 layers. The interlayer cation forms a strong bond between adjoining tetrahedral sheets, which limits expansion of the mineral. The mica group is subdivided into tri- and dioctahedral minerals according to cation substitutions in the octahedral sheet and within the interlayer. The trioctahedral group of micas contains interlayer K⁺ cations and is represented by phlogopite [KMg₃(AlSi₃O₁₀)(OH)₂], with Mg²⁺ occupying the octahedral sites, and biotite, which contains both Fe²⁺ and Mg²⁺ in the octahedron. Muscovite [KAl₂(AlSi₃O₁₀)(OH)₂] is a dioctahedral mica containing Al³⁺ in the octahedral sheet and K⁺ in the interlayer, while paragonite exhibits a similar

dioctahedral coordination with interlayer K⁺ and Na⁺ cations. In most soils, micas are generally inherited from the parent material and occur in a relatively unweathered state in the sand and silt fractions. Mica in the clay fraction usually exhibits poorer crystallinity, lower K⁺ content, higher water content, and possible substitutions of Fe²⁺ and Fe³⁺ in the octahedral sheets and Ca²⁺ in the interlayer. Manganese, vanadium, lithium, chromium, titanium, and several other cations are also known to occur in varying amounts in these fine-grained or clay-sized micas.^[1] Illite and glauconite (dioctahedral iron illites) are commonly associated with the clay-sized micas; however, the structures of these minerals are poorly defined and likely to be representative of a mixture of weathered micas. Expandable 2:1 clay minerals exhibit a similar layer structure to that described for mica but vary widely in layer charge and interlayer spacing due to the presence of weakly bound cations, water, or polar organic molecules in the interlayer region.

Smectites generally refer to a group of expandable dioctahedral 2:1 minerals with a charge of 0.2–0.6 per formula unit. Montmorillonite, the most common member of this group, derives its charge from the octahedral substitution of Mg²⁺ for Al³⁺. Beidellite and nontronite, which are less abundant in soils, derive much of their charge from tetrahedral substitutions. Nontronite is distinguished from beidellite by the presence of iron in the octahedral sheet. The 2:1 layers in smectites are held together by van der Waals bonds and weak cation-to-oxygen linkages. The presence of exchangeable cations located between water molecules in the interlayer allows for expansion of the crystal lattice as the mineral hydrates. When the mineral is saturated with water, the basal spacing between layers can approach 2 nm, while under dry conditions, the basal spacing may be reduced to less than 1 nm (Fig. 3). This expansion and contraction trait found in smectites, often referred to as shrink–swell potential, is problematic to engineers and farmers alike due to the propensity for crack formation and general instability of the soil surface.

The weathering of mica, via replacement of interlayer K⁺ with hydrated exchangeable cations, results in the formation of vermiculite. In soils, vermiculite exists as an Al³⁺-dominated dioctahedral and, to a lesser extent, Mg²⁺-dominated trioctahedral mineral. A charge of 0.6–0.9 per formula unit is derived in these minerals by tetrahedral substitution of Al³⁺ for Si⁴⁺. Consequently, vermiculites exhibit a high cation exchange capacity, particularly for weakly hydrated cations such as K⁺, NH₄⁺, and Cs⁺.^[5] Because of the tetrahedral charge origin, water molecules and exchangeable cations—primarily Mg²⁺ and Ca²⁺—are strongly adsorbed within the interlayer space of vermiculites. Unlike in smectites, the strong bonding of the interlayer cations holds the 2:1 layers together in vermiculites, thus limiting expansion of the basal spacing to 1.5 nm (Fig. 3).

Fig. 3 Schematic representation of (A) expandable dioctahedral montmorillonite; (B) expandable trioctahedral vermiculite; and (C) non-expandable trioctahedral chlorite.

2:1:1 Clay Minerals

Chlorites are a group of minerals that exhibit a basic 2:1 layer structure similar to that described for talc or pyrophyllite, but with an interlayer brucite- or gibbsite-like sheet, which forms a 2:1:1 structural arrangement. Isomorphic substitutions within the interlayer hydroxide sheet create a net positive charge that balances the negative charge arising from the 2:1 layers. A typical formula for the interlayer sheet is $(\text{MgFeAl})(\text{OH})_6^+$; however, a variety of cation species may exist in these brucite or gibbsite-like islands that contribute to a large number of mineral species within this group. There is no water adsorption within the interlayer space; thus, chlorites are considered non-expansive minerals (Fig. 3).

Hydroxy-Al Interlayered Vermiculites and Smectites

Chlorites exist in soils as primary minerals that weather to form vermiculite and smectite. In contrast, hydroxy-Al interlayered vermiculites or smectites are considered to be exclusively secondary minerals forming as intermediate mineral weathering products or from deposition of hydroxy-Al polymeric components within the interlayer space of expanding minerals.^[6] These hydroxy-Al polycations—with the general formula $\text{Al}_6(\text{OH})_{15}^{3+}$ —balance a portion of the charge but they are not exchangeable.

Because the level of hydroxy-Al occupancy within the interlayer space is variable, the CEC of the expandable 2:1 clays is reduced as a function of the quantity and valence of the hydroxy-Al polymer residing within the interlayer.

Mixed Minerals

In the soil environment, clay minerals rarely occur as homogeneous mixtures of single groups, types, or mineral phases. Instead, they comprise complex assemblages of primary minerals and weathering intermediates of multiple structural and compositional combinations. The potential also exists for a discrete mineral grain to be composed of more than one clay type or contain components that are intermediate between two known minerals. These minerals are referred to as mixed-layer or interstratified minerals. Examples of such mixed-layer mineral sequences include mica-vermiculite, mica-smectite, chlorite-vermiculite, and kaolinite-smectite, among others. The sequence of differing layers making up the mixed mineral occurs at both regular and random intervals. Consequently, efforts to fully characterize clay mineralogy within certain soils may be hindered considerably.

Other Clay Minerals

In addition to the phyllosilicates described, certain oxides, hydroxides, and hydroxy-oxides (sesquioxides) of Si, Al,

Fe, as well as some poorly crystalline aluminosilicates may also be found in small quantities in the soil clay fraction.^[7,8] Typical representatives of Si-oxide minerals that are often found in the clay fraction are quartz—due to its high resistance to weathering—and opal—a poorly crystalline polymorph of quartz, which precipitates from Si-supersaturated solutions or is of volcanic or biogenic origin. Gibbsite ($\text{Al}(\text{OH})_3$) is the main Al-hydroxide representative in clay fractions of highly weathered soils, while goethite (FeOOH) is the most common clay fraction Fe mineral. The poorly crystalline aluminosilicate clay minerals allophane and imogolite are typically found in clay fractions of soils derived from volcanic materials. Extensive discussions about these minerals and their properties are provided in other soil mineral sections of this encyclopedia.

Clay Mineral Identification and Quantification

The basic methods used for clay mineral identification and quantification involve X-ray diffraction (XRD) and thermal analyses.^[9] Electron microscopy is also employed for complementary mineral characterizations. In XRD analysis, the basal spacing (or d-spacing) between equivalent crystal planes is measured from the specific angle at which they diffract X rays of known wavelength according to Bragg's Law: ($d/n = \lambda / 2 \sin \theta$), where d = basal spacing, n = order of diffraction, usually set to 1, λ = X-ray wavelength, and θ = diffraction angle. Therefore, diffraction peaks at specific angles corresponding to fixed d-spacing characteristic of specific minerals are used for mineral identification, while diffraction peak intensities are utilized for quantitative estimations. The identification of minerals with overlapping d-spacing regions (smectite, vermiculite, and chlorite) is based on specific diffraction peak shifts, following solvation with specific ions and/or heating treatments.

Thermal methods are based on characteristic temperature regions in which specific minerals lose their structural OH water (thermogravimetric analysis) and the enthalpy associated with the dehydroxylation reaction (differential scanning calorimetry). Mineral quantities are estimated from comparisons of the OH- or enthalpy fractions that have been measured and standard quantities of representative pure minerals.

Clay Minerals: Charge Properties

Christopher John Matocha

Agronomy Department, University of Kentucky, Lexington, Kentucky, U.S.A.

Abstract

Surfaces of soil particles are classified as having either permanent charge or pH-dependent charge. A permanent charge is derived from isomorphous substitutions in the mineral structure and is indifferent to the conditions surrounding the mineral. Isomorphous substitution involves the replacement of constituent metal ions of the lattice by cations of lower charge, generating a net negative charge on the mineral, which is compensated by the positive charge of adsorbed (exchangeable) cations. The substitution can occur during or after crystal formation. Surface functional groups that may be exposed on the periphery of minerals protonate and deprotonate depending on the solution pH, generating pH-dependent surface charge. Most soils carry a net negative charge because of negative charges on phyllosilicate minerals, but some weathered soils can develop a net positive charge at sufficiently low pH due to the presence of hydrous iron and aluminum oxides. The net negative charge on soil minerals produces a positive electrostatic attraction for cations in soil solution that are retained on the surface. The total quantity of cations retained in this way is called the cation exchange capacity because they are easily exchanged with other cations. The focus of this entry is the surface charge properties of 1:1 and 2:1 phyllosilicate minerals because of their abundance and significant influence on agricultural and environmental processes.

ORIGINS OF CHARGE

Phyllosilicate minerals consist of aluminosilicate tetrahedral and octahedral sheets stacked one above the other and differentiated by the number and combination of sheets and the cation substitution in each sheet.^[1,2] In 1:1 phyllosilicate minerals, such as kaolinite, the full-cell chemical formula is $\text{Si}_4\text{Al}_4\text{O}_{10}(\text{OH})_8$ where one silica tetrahedral sheet is combined with one aluminum octahedral sheet and individual layers stack by hydrogen bonding (O–H–O) in the c-dimension (perpendicular to the plane of the sheets) with a combined thickness of 0.7 nm. Generally, no isomorphous substitution occurs in either sheet; thus, kaolinite has no significant permanent negative structural charge on basal sites and little cation exchange capacity (CEC).^[1] Where crystal growth stops and no more unit cells are added, broken bonds exist on the edges of clay minerals and a surface is obtained (Fig. 1). These “edge” sites exhibit pH-dependent charge that results from protonation/deprotonation of aluminol ($>\text{AlOH}$) and silanol ($>\text{SiOH}$), functional groups that are exposed on the periphery or edges of the mineral.^[4] The acidity or dissociation constants ($\text{p}K_{\text{a}}$ s) for the aluminol edge sites are $\text{p}K_{\text{a}1} = 6.3$ and $\text{p}K_{\text{a}2} = 8.7$, meaning that at $\text{pH} < 6$, these edge sites are positively charged.^[5] This explains the early findings of Schofield and Samson,^[6] who documented Cl^- sorption at low pH. Kaolinite has a significant concentration of edge sites because it tends to stack in the c-dimension.^[4]

The 2:1 phyllosilicate minerals consist of two tetrahedral sheets that sandwich one octahedral sheet (Fig. 1). The ideal full-cell chemical formula for 2:1 clay would be $\text{Si}_8^{\text{IV}}\text{Al}_4^{\text{VI}}\text{O}_{20}(\text{OH})_4$, where the roman numerals refer to the tetrahedral (IV) and octahedral (VI) sheets, respectively.^[7] This formula is represented by the mineral pyrophyllite, which is neutral because no cation substitution occurs in either sheet. More common 2:1 phyllosilicate minerals include the smectite and vermiculite groups. The number of cation positions occupied within the octahedral sheet determines whether a clay mineral is di- or trioctahedral. If Al^{3+} is present in the octahedral sheet, then the mineral is dioctahedral, and if Mg^{2+} is present, then the mineral is trioctahedral. Within the smectite group of minerals, dioctahedral montmorillonites have the majority of structural negative charges. These are derived primarily from octahedral site substitutions of Fe^{2+} or Mg^{2+} for Al^{3+} with a structural formula of $\text{Si}_8^{\text{IV}}\text{M}_{0.66}\text{H}_2\text{OAl}_{3.34}^{\text{VI}}(\text{Fe}^{2+}, \text{Mg}^{2+})_{0.66}\text{O}_{20}(\text{OH})_4$, where M refers to the exchangeable cation balancing the permanent charge produced by the substitution of Fe^{2+} or Mg^{2+} for Al^{3+} .^[3] The octahedral layer charge for montmorillonite, or the number of moles of excess electron charge per formula unit,^[1] would be -0.66 , balanced by $\text{M}_{0.66}$ exchangeable cations adsorbed near the basal plane of the tetrahedral sheet. In dioctahedral beidellites, tetrahedral substitutions of Al^{3+} for Si^{4+} exceed substitutions in the octahedral sheet (Fig. 1). Nontronite is similar to beidellite except it has redox-active Fe^{3+} in octahedral coordination (Fig. 1). The vermiculite group differs from

Fig. 1 Representative 2:1 phyllosilicate minerals indicating charge sites and different locations of substitution.

Source: From Borchardt.^[3]

the smectite group because the primary source of negative charge arises from a large degree of Al^{3+} for Si^{4+} substitution in the tetrahedral layer, giving rise to a layer charge greater than that in smectites, ranging from 1.2 to 1.8.

The basal plane of a tetrahedral sheet composed of oxygen atoms is called the siloxane surface, and its reactivity depends on the location and type of isomorphous substitution.^[8] In a tetrahedrally substituted clay such as beidellite, the excess negative charge is localized and functions as a strong electron donor because of the lone pair, non-bonding electrons on the siloxane oxygens.^[8,9] Siloxane oxygens not adjacent to the site of substitution, as is the case for octahedrally substituted montmorillonite, are weaker electron donors because the negative charge is distributed over at least 10 surface oxygens.^[9]

One characteristic that the smectite and vermiculite groups have in common with kaolinite is the presence of edge sites, although in lower concentration because stacking occurs predominantly in the horizontal dimensions (a, b) rather than the vertical c-dimension. A distinguishing feature of the smectite and vermiculite groups from kaolinite is the presence of an interlayer, occupied by exchangeable cations such as Ca^{2+} and water (Fig. 1). Thus, the 2:1 clay mineral particles have external planar

sites, internal sites, and edge sites, while kaolinite contains mainly external edge sites. The active interlayer and the higher level of isomorphous substitution give rise to greater CEC values for smectite and vermiculite minerals ($\text{CEC} \sim 0.80\text{--}1.50 \text{ mEq g}^{-1}$) when compared to kaolinite ($\text{CEC} \sim 0.02\text{--}0.05 \text{ mEq g}^{-1}$).

SURFACE CHARGE DENSITY OF CLAY MINERALS

It is important to note at this point that the clay size fraction is, by definition, any mineral with a particle size $<2 \mu\text{m}$. Thus, the clay size fraction has a large amount of surface area per unit mass when compared to the silt and sand fractions. This is clearly shown when one derives the specific surface area, or the area per unit mass. For uniform, spherical particles, this ratio equals

$$S = 3/\rho R$$

where S is the specific surface area ($\text{cm}^2 \text{g}^{-1}$) having a radius R (cm) and a particle density ρ (g cm^{-3}). For a given particle size, an equal mass of smectite or vermiculite would have a greater specific surface area when compared to kaolinite because of the presence of the interlayer. A typical value of S for montmorillonite would be $700 \text{ m}^2 \text{g}^{-1}$, while for kaolinite S is considerably less ($\sim 10 \text{ m}^2 \text{g}^{-1}$). The surface density of charge, obtained by normalizing the CEC to S , is similar irrespective of clay mineral type because S tends to scale with CEC.^[10] Higher S values usually indicate greater potential for reactivity.

AGRICULTURAL AND ENVIRONMENTAL IMPLICATIONS OF SURFACE CHARGE

High-Activity and Low-Activity Clays

Small amounts of smectite minerals can greatly influence overall soil charge properties due to their greater specific surface area. In the context of charge, clay activity classes have been defined as the ratio of CEC/clay content.^[11] High-activity clay minerals, such as smectite or vermiculite, have ratios >0.7 , while low-activity clays like kaolinite have ratios <0.3 . These indices are useful in estimating mineralogy when no specific mineralogy data are available.^[11]

Adsorption of Plant Nutrients and Contaminants

As mentioned earlier, the cations balancing the net negative charge generated from isomorphous substitutions in order to maintain electroneutrality are exchangeable. They maintain their inner hydration shell, thus forming the so-called outer-sphere complexes.^[8] An example of an outer-sphere

complex would be exchangeable Ca^{2+} in the interlayer space of 2:1 minerals (Fig. 1). Exchangeable cations are agronomically important because they are available to plants. In contrast, cations that lose H_2O from their inner hydration shell to form a direct bond with a mineral surface functional group are inner-sphere surface complexes.^[8] The type of surface complex formed influences the fate of plant nutrients and contaminants in the soil environment.

Tetrahedrally substituted clay minerals can form stronger adsorption complexes with cations than octahedrally substituted clay minerals.^[1] Cations with the largest ionic radius and lowest hydration energy are preferentially adsorbed on permanent charge sites.^[10] Vermiculites and beidellites, with more tetrahedral charge sites, can fix K^+ more readily by forming inner-sphere bonds with siloxane oxygens. The fixation of K^+ makes it unavailable to plants because formation of these bonds causes the collapse of adjacent silicate layers.^[6] The proximity of tetrahedral charge to the interlayer space of 2:1 phyllosilicates explains the greater K^+ -fixing ability of tetrahedrally charged clays.^[12]

Varying pH and background electrolyte concentration is an approach used to assess the contribution of pH-dependent charge edge sites and permanent charge sites in controlling metal contaminant solubility on montmorillonite. Spectroscopic investigations confirmed that Pb^{2+} and Cu^{2+} adsorbed as inner-sphere surface complexes on hydroxyl edge sites in montmorillonite, particularly when pH and ionic strength increased, and as outer-sphere surface complexes on permanent charge sites at low pH and less ionic strength.^[13,14] The inner-sphere Cu^{2+} complexes coordinated to the hydroxyl edge sites were resistant to desorption, whereas outer-sphere Cu^{2+} surface complexes on permanent charge sites were exchangeable and potentially more mobile. Therefore, the practical benefit achieved in considering the difference between outer-sphere and inner-sphere surface complexation would be in predicting the fate of plant nutrients and contaminants in the soil environment.

Flocculation Processes

Clay particle–particle interactions regulate dispersion and flocculation processes and are important to soil quality. Flocculation, by definition, is the formation of particle aggregates from the association of individual particles in water that settle by gravity and promote aggregation and optimal soil structure.^[10] Positively charged clay mineral edges contribute to flocculation, because of the electrostatic attraction between positive edges and negative planar surface faces of adjacent minerals. Studies of the Schofield and Samson^[5] showed that kaolinite can be deflocculated by the addition of montmorillonite particles. Other factors influencing the degree of flocculation include charge of exchangeable cation, ionic strength of the soil solution, and

cation size. High-charge exchangeable cations and high ionic strength promote flocculation of clay mineral suspensions dominated by permanent charge minerals.^[10] High Ca^{2+} status and near-neutral pH are associated with stable aggregation in less weathered soils carrying a net negative charge. There is a direct relationship between cation size and ability to form inner-sphere surface complexes with clay mineral sites. For instance, high concentrations of exchangeable Na^+ promote dispersion and poor structure because it is weakly adsorbed, likely bound as an outer-sphere surface complex with octahedral charge sites on smectites.^[11] The greater hydration of Na^+ , a function of its small ion size, explains the weaker retention of Na^+ when compared to larger cations like Cs^+ .^[10]

Clay Swelling

Water penetrates the interlayer of 2:1 phyllosilicates and forces them apart, causing the clay to swell, which is an important natural soil phenomenon. High-activity clay minerals, such as montmorillonite, influence the engineering behavior of soils because of their ability to take up and adsorb large amounts of water, when compared to low-activity clay minerals like kaolinite.^[11] Water adsorption is an exothermic process, thus “heat of wetting” values are typically greater for montmorillonite than for kaolinite. In addition, the type of exchangeable cation and location and distribution of charge strongly influence hydration characteristics of the clay mineral. The amount of water adsorbed and internal surface hydrated on montmorillonite is positively correlated with hydration energy of the exchangeable cation.^[15] Sodium (Na) montmorillonite exhibited greater adsorption–desorption hysteresis of water when compared to calcium (Ca) montmorillonite and magnesium (Mg) montmorillonite, which was ascribed to differences in hydration energy for the cations.^[16] Well-hydrated interlayer Ca and Mg serve to prop open the interlayer when compared to Na montmorillonite. The ability of montmorillonite to swell in water more than vermiculite, despite the greater layer charge in the latter mineral, is explained by the location of the charge. The localized charge in tetrahedrally substituted vermiculite apparently causes the exchangeable cations to pull the layers together and limit the expansion.^[10]

Clay Minerals: Weathering and Alteration of

Anastasios D. Karathanasis

Department of Agronomy, University of Kentucky, Lexington, Kentucky, U.S.A.

Abstract

Mineral weathering encompasses the physical and chemical breakdown of minerals that are unstable under the conditions prevailing at the earth's surface. It is driven by physical, chemical, and biological gradients, which cause gradual structural and compositional mineral alterations that allow them to attain more stable states. Most weathering reactions lead into complete dissolution of the original mineral structure to soluble components, which resynthesize to form a new mineral with different composition. A significant number of mineral alterations, however, result in modified residual mineral structures without going through a complete dissolution phase. Water (H_2O) is the main mineral weathering agent. Under its dominant influence, physical forces (wetting and drying, freezing and thawing, wind and H_2O erosion, thermal expansion, and salt crystallization) combine with chemical forces (hydration–dehydration, acidification, oxidation–reduction, and chelation) to produce new mineral phases more conforming to the existing environment.

MINERAL RESISTANCE TO WEATHERING

Weathering affects both primary and secondary minerals. Primary minerals having formed under high temperature and pressure conditions are less stable under ambient conditions and tend to transform into secondary minerals. Their resistance to weathering is inversely related to the temperature of their crystallization from cooling magmas. The higher the temperature of formation, the lower their stability at the surface of the earth. Based on this principle, Goldich^[1] proposed a stability series of common primary minerals (Table 1), which was experimentally confirmed with long-term mineral dissolution comparisons.^[2] Mineral stability is also a function of structural bond strength with which atoms and ions are held together in the crystal lattice of each mineral. Most primary minerals are silicates or aluminosilicates, with strong silicon–oxygen (Si–O) bonds, moderately strong aluminum (Al)–O bonds, and weaker metal–O bonds in their crystal lattice. Their susceptibility to weathering depends on the number of weak bonds and the strength of the Si–O bond, which is a function of the Si–O ratio in the structure. The lower the ratio (increased sharing of O between adjacent silica tetrahedrons) the stronger the overall mineral structure. Quartz, e.g., having the maximum sharing of tetrahedral O, is one of the most resistant minerals. Olivine is one of the most weatherable minerals because there is no sharing of O in its structure. The stability of other minerals is controlled by the number of shared O and the type of cation bonds satisfying isomorphic substitutions within the structure. In addition, the presence of iron (Fe) and manganese (Mn) in the lattice usually induces higher weatherability because oxidation–reduction transitions create charge imbalances within the structure. Keller^[3] and Birkeland^[4] used the following mineral

stability sequence to rank the silicate mineral groups according to bond strength considerations: nesosilicates ($\text{Si–O} = 1/4$) < single-chain inosilicates ($\text{Si–O} = 1/3$) < double-chain inosilicates ($\text{Si–O} = 4/11$) < phyllosilicates ($\text{Si–O} = 2/5$) < tectosilicates ($\text{Si–O} = 1/2$). Even though some discrepancies exist between the crystallization temperature and the Si–O bond strength sequences, these two schemes are used extensively for making mineral weathering stability interpretations.

Weathering continues after the transformation of primary to secondary minerals because some of them may be stable only within a certain range of solution ionic gradients. As the concentration of soluble Si, Al, and other cations decreases through leaching processes, initially stable secondary minerals may weather further to more stable states. Therefore, secondary minerals may be the products of alteration of primary or secondary minerals subjected to multiple weathering cycles. Jackson and Sherman^[5] proposed a mineral weathering sequence based on the relative degree of soil development with continuous leaching and the types of minerals commonly found in the soil clay fraction (Table 2). This weathering scheme or stages of it may be applicable to many soils, but it does not specify the physicochemical gradients that could trigger a certain set of transformations, or whether a given soil under specific environmental conditions will go through every one of the predicted stages. Nevertheless, it has been an effective tool in describing soil development stages and processes mainly because the clay fraction minerals play a greater role and are more actively involved than their sand and silt size counterparts in the changes occurring in the soil over time. Furthermore, the clay minerals due to their smaller size, high surface area, and chemical activity are in closest agreement with the surrounding soil solution composition, which

is the driving force for mineralogical changes. The mineral groups of the clay size fraction listed in Table 2 indicate progressively increasing stages of soil development. A certain mineral suite may not include all the minerals of a specific weathering stage or index or may not necessarily dominate the clay fraction in order to be a fairly reliable indicator of the overall weathering or maturity status of a soil. A given soil clay fraction often contains a mixture of minerals covering several adjacent weathering stages. A quantitative weathering mean representing the weighted average of mineral composition by soil horizon depth is used to estimate the overall weathering stage of soil development.^[6] In most soils, this mean generally shifts from lower to higher numerical weathering stages as the particle size decreases, as we move from the parent material to the soil surface, and as the soil advances in maturity. With continuous weathering and sufficient time, the effect of distinct climatic and geographic settings should be more evident in the distribution of soil clay minerals. Indeed,

these relationships have been the foundation for developing various soil classification schemes, grouping soils with similar behavior, including Soil Taxonomy.^[7]

MINERAL WEATHERING PATHWAYS

Regardless of the mineralogical and structural composition of the minerals undergoing weathering, the degree of alteration and mineral weathering products depend on the intensity and extent of leaching by water (H₂O). Differences in the chemical composition between the leaching H₂O and the mineral structures provide the chemical energy to initiate and sustain mineral changes. The rate of leaching controls the composition of the aqueous solution by dictating the rate of removal of the dissolved solutes, and hence the course of the mineral alteration. In regions of limited rainfall, where evapotranspiration exceeds precipitation, the downward flow of H₂O through a soil-containing soluble salts and carbonates is sufficient only in removing the most soluble weathering products, such as sodium (Na) salts. Less soluble minerals tend to form and accumulate in lower soil depths because of limited leaching. Soluble potassium (K) and magnesium (Mg) may form secondary aluminosilicates, while soluble calcium (Ca) may reprecipitate as calcite or gypsum. Secondary calcite precipitation is induced by lower carbon dioxide (CO₂) pressure and higher pH below the soil surface. The accumulation of secondary carbonates in the soil results in considerable inhibition of silicate mineral weathering because of their control of pH and soluble Ca concentrations.

The main weathering pathway for silicate minerals is desilication. Part of the Si released from the mineral structure reacts with Al and to a lesser extent with Fe or Mg to form other clay minerals, while the remainder is subject to leaching. Consequently, most soils experience a loss of Si and basic cations during weathering, which results in a relative increase and residual accumulation of Al- and Fe-enriched mineral structures (ferrallitization; Fig. 1). Desilication is more pronounced in humid tropical environments, but it occurs with lesser intensity in temperate regions as well. Upon desilication and release of Mg and Fe, olivines weather mainly to serpentine and subsequently smectite and goethite.^[8] Similarly, pyroxenes and amphiboles weather through loss of Mg, Fe, and Ca to chlorite and smectite. Under stronger leaching conditions, all three of these mineral groups may produce more advanced weathering mineral products, such as kaolinite, halloysite, and various oxyhydroxides.^[7] Trioctahedral micas (biotite and phlogopite) weather more readily than dioctahedral micas (muscovite and illite) through K release and charge reduction to form interstratified mica-vermiculite, vermiculite, and subsequently smectite.^[8,9] Upon stronger weathering under tropical and subtropical conditions, trioctahedral micas may ultimately form kaolinite and halloysite as well as goethite and hematite. The weathering stages of

Fig. 1 A generalized mineral weathering/formation pathway scheme.

trioctahedral chlorites are analogous to those of trioctahedral micas, producing interstratified chlorite-vermiculite, vermiculite, smectite, halloysite, kaolinite, and Fe-oxyhydroxides.^[7-9] Dioctahedral micas (muscovite and illite) undergo similar transformations upon weathering to those discussed for trioctahedral micas. However, their intermediate and advanced weathering products are clearly dioctahedral. Furthermore, under the conditions of active leaching, moderately acidic conditions, and low organic carbon content, their vermiculite and smectite weathering products may transform into Al-hydroxyinterlayered versions as a result of Al-hydroxide polymerization within their interlayer spaces.^[7] These minerals, sometimes known as pedogenic chlorites, have a lower charge but display considerably greater stability in the weathering environment.^[10]

Feldspar weathering could lead into a variety of mineral products, including sericite (a micaceous mineral), interstratified mica-smectite, smectite, and a variety of 2:1 aluminosilicates.^[7,11,12] Most often, however, feldspars weather to kaolinite, halloysite, gibbsite, and even quartz.^[9,12] Slow rates of leaching through the feldspar grains usually form 2:1 phyllosilicates, while high rates of leaching induce gibbsite formation.

While vermiculite is considered mostly as an intermediate product of the transformation of primary or secondary mica minerals, smectites can be inherited from parent materials or form either by transformation of other

2:1 phyllosilicates (micas and vermiculite) or by precipitation from saturated solutions.^[7,9] Transformations from other 2:1 minerals usually occur under high leaching acidic environments, whereas neoformation is induced by poor drainage conditions and the accumulation of necessary cations and silica. Under prolonged acidic conditions, vermiculites may transform to smectites through interlayering, while smectites may alter to kaolinite or halloysite following various stages of interstratification.^[9,13] Smectite to kaolinite transformations may involve several stages of interlayering of smectite with various kaolinite precursor phases.^[7,13] Both vermiculite and smectite may also form Al-hydroxyinterlayer phases, which enhance their stability in intense weathering environments. Kaolinite may also form via precipitation from solution under warm or temperate humid conditions, while halloysite neoformation has been often associated with weathering of volcanic materials.^[7] Under extreme desilication conditions and low residence time of Si in the soil solution, gibbsite instead of kaolinite may form. The reverse transformations of gibbsite to kaolinite and kaolinite to smectite in environments experiencing resilication have also been reported. The nature of Fe oxides and oxyhydroxides formed through mineral weathering processes depends mostly on the environmental conditions and less on the structure of the dissolved mineral. Accumulation occurs in well-oxidized environments in the Fe(III) form, while remobilization occurs under anaerobic conditions in the Fe(II) form.^[14] Goethite

formation is usually favored under cool temperate conditions with moderate organic carbon content, while hematite prefers low organic carbon, warmer, and drier environments. Finally, the most stable titanium (Ti) and zirconium (Zr) minerals are the ultimate products of weathering, which accumulate residually in the soil as a result of the dissolution of silicate minerals containing Ti and Zr mainly as impurities in their structure.^[7] Because of their high stability, these minerals are used as indexes of soil development stages and soil age.

THERMODYNAMIC FORMULATIONS OF MINERAL WEATHERING

Based on the principle that the stability of a mineral in the weathering environment depends on the balance or imbalance of its structural ions with the activities of the common ions in the soil solution, Kittrick^[15] developed a thermodynamic approach in predicting mineral stability. The approach involves the formulation of mineral stability lines in terms of major ionic constituents from dissolution–precipitation reactions and plotting them in a stability diagram. For relatively simple aluminosilicate minerals, such diagrams are plotted as functions of $\text{pH} + 1/3 \log \text{Al}^{3+}$ and $\log \text{H}_4\text{SiO}_4$ supported by different minerals from which their stability is deduced under specific ranges of solution ionic conditions (Fig. 2). For minerals with additional structural elements, a fixed nominal range in their activity is assumed, so that their stability lines are expressed in terms of major structural ions only (Al and Si) and pH, and be comparable to those of other minerals. The stability of a given mineral under a specific soil environment is determined from the solution composition coordinates in terms of $\text{pH} + 1/3 \log \text{Al}^{3+}$ and $\log \text{H}_4\text{SiO}_4$ plotted in the diagram. Solution points plotted along a mineral stability line are considered in equilibrium with the mineral, while points plotted above (also to the right) or below (also to the left) the line represent environments in which the specific mineral is stable or unstable, respectively. Since desilication

generally produces more stable minerals, as a convention, the most stable mineral in a stability diagram is the one supporting the lowest level of $\text{pH} + 1/3 \log \text{Al}^{3+}$ for a given level of $\log \text{H}_4\text{SiO}_4$. In the stability diagram of Fig. 2, at $\log \text{H}_4\text{SiO}_4 = -3.5$, the mineral supporting the lowest $\text{pH} + 1/3 \log \text{Al}^{3+}$ and, therefore, the most stable is kaolinite. Similar thermodynamic stability concepts have been used for non-silicate minerals in a variety of geochemical and environmental applications.^[16]

MECHANISMS AND RATES OF MINERAL WEATHERING

Important mechanisms of mineral weathering include dissolution–precipitation, hydrolysis, oxidation–reduction, hydration–dehydration, chelation, and ion exchange.^[4] Dissolution reactions could be congruent or incongruent. During congruent dissolution, the mineral goes into solution completely with no concurrent precipitation of other minerals. In contrast, with incongruent dissolution, all or some of the ions released by weathering precipitate to form new minerals. Relatively soluble minerals (salts, gypsum, and carbonates) and most silicate minerals dissolve congruently, while most aluminosilicate minerals weather through incongruent dissolution reactions. Hydrolysis involves the interaction and replacement of structural cations with H^+ ions dissociated from H_2O . This exchange has a disrupting effect on the crystal surface because of the high charge to ion size ratio of H^+ and weakens the rigidity of the mineral structure. Hydrolysis is the main mechanism in the weathering of feldspars and other aluminosilicates. Minerals containing Fe, Mn, or sulfur (S) are especially susceptible to oxidation–reduction reactions. Oxidation involves the loss of electrons, and therefore, changes in charge. The disruption of the crystal electrostatic neutrality along with the size change of the same element at different oxidation states causes considerable instability in the crystal lattice and makes the mineral more susceptible to weathering. Hydration and dehydration involve the addition or removal of H_2O molecules in the crystal structure of a mineral. They are not as important weathering mechanisms because they affect very few minerals. Examples are the formation of gypsum and anhydrite or halloysite and kaolinite following hydration–dehydration. Complexation is the process by which chelating agents produced through soil biological processes interact with structural cations to form stable ligands and remove them into solution. The process, which affects many clay minerals, destabilizes the mineral structure and facilitates further decomposition. Ion exchange between the solution and mineral surfaces does not produce drastic alterations, since it leaves the mineral structure unchanged, but hydration differences between exchanged ions may cause considerable changes in the physicochemical properties of the interlayer space.

Fig. 2 A typical thermodynamic mineral stability diagram for common soil clay minerals.

Temperature, moisture flux, and solution gradients are the major environmental variables affecting mineral weathering rates. Additional factors include mineral particle surface area and biological activity. Generally, weathering rates increase with temperature, intense leaching and removal of soluble products, surface area, and biological activity. The rate of weathering of silicate minerals is very slow, with average lifetimes ranging from 2.3×10^3 for olivine to 2.4×10^7 for quartz considering 1-mm diameter crystals under pH = 5.0 and 25°C.^[17] This suggests that the bulk mineralogy of a soil is not expected to change considerably during the life span of any given individual. Relative weathering rates are generally consistent with the mineral stability sequences reported earlier, but natural rates are usually several orders of magnitude lower than laboratory estimated rates.^[17] One of the main reasons is that natural systems experience variable moisture fluxes and periodic replenishment compared to the steady flows used during laboratory experiments. Also, the presence and distribution of structural defects and crystal imperfections enhance significantly mineral dissolution rates. Therefore, quite variable dissolution rates may be obtained for the same mineral depending on its degree of crystallinity.

PRACTICAL IMPLICATIONS OF MINERAL WEATHERING

Mineral weathering sequences have been important models in explaining soil development stages over time and understanding respective pedochemical processes. Thermodynamic approaches of mineral weathering have allowed the assessments of existing mineral stability trends and the predictions of future changes in soil ecosystems, as they are impacted by shifts in use and management.^[16] Mineral weathering is also the process contributing several macronutrients, such as Ca, Mg, K, P, and S and most micronutrients to the soil, as they are released from dissolving minerals. Ultimately, these elements are used and recycled by plant communities or leached out of the rooting zone, thus providing an important link between the soil fertility status and degree of mineral weathering. Weathering of silicate minerals also plays an important role in buffering watershed acidification from atmospheric inputs. This is the only process by which the long-term neutralization of produced acidity is achieved through continuous release and replenishment of basic cations from mineral weathering. Global climatic changes are also affected by mineral weathering processes.^[18] On geological timescales, atmospheric CO₂ levels have been primarily controlled by the balance of volcanic inputs from the earth's interior and silicate weathering outputs at the earth's surface. This balance has been disturbed by burning large quantities of fossil

fuel. It will be interesting to see whether the greenhouse effect will be able to trigger high enough silicate weathering rates able to moderate or buffer larger global climatic changes.

Abstract

Climate is a versatile factor that affects virtually all pedogenetic phenomena. Climatic conditions specify the amounts of solar radiation and precipitation getting to the soil surface. Solar radiation is the main source of energy for most of the processes in the pedosphere. The degree of transformation of soil mineral mass, the rate and character of decomposition of organic remains in the soil, and the nature and functioning of soil biota depend on the supply of solar radiation to the soil, provided that the soil gets a sufficient amount of moisture. Annual precipitation and its distribution by separate seasons together with the evapotranspiration value dictate the degree of soil moistening, the depth of water percolation, the reserves of water in plants, and the water supply of soil microbiota. The dependence of soils on climate is manifested by the climatic zonality of the soil cover, i.e., by the distribution of particular soils over the earth's surface in agreement with thermal belts and regions of different moisture levels. Climatic zonality is one of the main regularities in the development of soil cover patterns.

HISTORICAL BACKGROUND

Since the end of the 19th century, special in-depth studies of the role of climate as a factor that controls the supply of energy and moisture to soil have been conducted by soil scientists. In 1883, Dokuchaev advanced the concept of soil forming factors in his classical monograph *Russian Chernozem*.^[1] Along with climate, he considered parent rocks, living organisms, relief, and time to be equally important obligatory factors for soil formation. At the same time, it was climate that received Dokuchaev's primary attention. The student and follower of Dokuchaev, N.M. Sibirtsev considered climate as the most important soil forming factor. The system of soil classification developed in 1898 by Sibirtsev^[2] stressed the priority of climatic factors. At approximately the same time the works of E.W. Hilgard on the role of climate in soil formation appeared in the United States. Hilgard paid special attention to the study of soil temperature and moisture conditions and their effect on soil processes. The results of these studies were summarized in his works. *A Report on the Relations of Soil to Climate*^[3] and *Soils: Their Formation, Properties, Composition, and Relation to Climate and Plant Growth in the Humid and Arid Regions*.^[4] Later, numerous empirical relationships between various soil properties (the contents of humus, carbonates, nitrogen, clay, saturation capacity, acidity, silica-to-alumina ratio, etc.) and the main climatic parameters (annual precipitation and mean annual temperature) were analyzed by H. Jenny. Jenny suggested the equation of soil forming factors in which the contributions of the

inner (soil) and outer (atmosphere) climate to soil formation were considered, respectively, as the components of the internal and external potentials of pedogenesis.^[5,6] V.R. Volobuev suggested the concept of hydrothermic sequences of soils. He revealed global relationships between the distribution of soils and ecosystems and several climatic parameters (annual precipitation, mean annual temperature, radiation balance, and evaporation capacity).^[7] V.A. Kovda stressed that, in contrast to all the other factors of soil formation having terrestrial origin, the climate is governed by cosmic factors.^[8] He emphasized the need to study soil evolution as related to climate changes in the earth's history. S.W. Buol, F.D. Hole, and R.J. McCracken considered climate (together with living organisms) in the group of *flux factors* responsible for the transfer across a surface of interface of energy, fluids, particles, and other entities.^[9] M.A. Glazovskaya and A.N. Gennadiyev analyzed the contribution of climate to the energy state of soils, their material basis, and the dynamics of soil forming processes.^[10]

It is firmly established that the great diversity of soils on our planet is connected to the diversity of climatic conditions.

DISCUSSION

The annual sum of active (above 10°C) air temperatures (accumulated active temperature), mean annual temperatures, and the indices of radiation balance increases by tens and even hundreds of times from polar regions to the

equator. This results in considerable differences between polar and tropical regions with respect to the thermal state of soils and the climatic potential of pedogenesis. According to Van't Hoff's Law, a 10°C rise in temperature accelerates the rate of chemical reactions by 2 to 3 times. It means that the intensity of chemical reactions, including the weathering of minerals, decomposition of organic matter, and the synthesis of new organomineral compounds, in the soils of tropical regions is tens of times higher than in cold polar regions. Therefore, the thickness of soil profiles and weathering crusts in the tropics is much greater than that in temperate and cold regions of the earth.

The input of solar radiation to the earth's surface proceeds with varying intensity, displaying diurnal, seasonal, annual, and long-term fluctuations (cycles). Therefore, periods of soil heating alternate with periods of soil cooling; in many regions, the alternation between soil thawing and freezing is observed. Various combinations of these processes together with particular temperature conditions in the soil specify the *heat (or temperature) regimes of soils*.

In soils that remain in a frozen state for a long period, the possibilities for the development of soil forming processes are strongly restricted in time: at low temperatures, chemical reactions proceed very slowly or cease, the activity of living organisms is decelerated, and the migration of soil solutions stops. At the same time, soil material may be subjected to cryogenic churning (*cryoturbation*). In contrast, long periods with relatively high temperature favor the development of diverse pedogenetic processes.

The soil temperature regime is conditioned by the direct supply of solar radiation, as well as by the peculiarities of atmospheric circulation, including the advection of warm or cool air masses.

The pedogenetic and biological effects of the heat transmitted from the Sun to the earth's surface can only manifest themselves in full measure if the moisture supply of the soil is sufficient. Atmospheric precipitation is the main factor controlling the solution, leaching, and migration of mobile compounds in the soils. The hydrolysis of primary minerals and the synthesis of secondary clay minerals in soils occur due to the supply of water. Atmospheric water that reaches the soil is retained in soil horizons and consumed by plants in the course of photosynthesis. The biomass produced by plants serves as a source of energy and nutrients for animals and microorganisms. Thus, precipitation is directly and indirectly related to the processes of humus formation in the soils. Eventually, the degree of soil water supply dictates the development of the main genetic horizons of soils, i.e., humus-accumulative, eluvial (horizons with predominant leaching), metamorphic, and illuvial (whose accumulation of substances leached from the above-lying horizons takes place) horizons. Different types of *soil water regime* can be distinguished on the basis of data on the depth and intensity of water migration and the predominance of ascending or descending water flows in the soil. The many-sided role of atmospheric precipitation in the

Fig. 1 Relation between depth of carbonate accumulation and rainfall in loessial soils. Every point represents the depth of the beginning of the concretion zone in a soil cut investigated.

pedogenetic process is shown in Figs. 1 and 2. The effect of precipitation on soil properties is so significant that it can be indirectly reflected in soil classification. Thus, C. Marbut suggested that all soils could be subdivided at the highest level into two groups, namely, Pedalfers and Pedocals.^[11] Pedalfers included the soils of tundra, taiga, and tropical rainforests, i.e., territories with sufficient or excessive moistening. Intensive leaching of soluble compounds in Pedalfers leads to residual accumulation of less soluble sesquioxides (aluminum and iron). Pedocals

Fig. 3 Marbut's classification of soils into Pedocals and Pedalfers.

Source: From Jenny.^[5]

included the soils of steppes, semideserts, and deserts with insufficient moistening and accumulation of calcium carbonates in the profile (Fig. 3). The leading role of the moisture factor in soil development is especially stressed by I.A. Sokolov.^[12] According to Sokolov, two fundamentally different worlds of soils can be distinguished: the world (pedocosmos) of arid pedogenesis and the world of humid pedogenesis. Arid pedocosmos consists of accumulative, saturated, neutral or alkaline, calcareous, and/or saline xeromorphic soils. Humid pedocosmos is the world of eluvial, leached, acid, and unsaturated soils.

Variations in annual precipitation across the globe are very considerable. A general trend toward an increase in precipitation from polar regions to the equator (i.e., in the same direction as mean annual air and soil temperatures) is observed. However, the input of solar radiation, and, hence, the heat supply of soils, has a rather distinct latitudinal (zonal) pattern, whereas the zonal distribution of precipitation is strongly altered by the particular geomorphic conditions (the distance from the sea, the location of mountain chains), general circulation of the atmosphere, ocean currents, etc. The overall effect of precipitation and temperature on soil formation has an extremely complex character.

Initially, the most general regularities of soil distribution dependent on spatial changes in moisture and temperature conditions were formulated by Dokuchaev in the form of the Law of Horizontal (for plain territories) and Vertical (for mountains) Soil Zonality. Later, with acquisition of new factual data, this initial perception of soil zonality was refined and shaped into a more complex form. In 1933, I. P. Gerasimov formulated the concept of bioclimatic soil facies. He stressed that local provincial (facial) peculiarities of the climate conditioned by local thermodynamic processes in the atmosphere complicate the latitudinal pattern of soil zonality.

In works devoted to geographic division (regionalization) of the soil cover of the planet and particular regions, much attention has been paid to climatic criteria of such division. Thus, M.A. Glazovskaya^[13] separated the

pedosphere into *pedobioclimatic belts* encompassing horizontal soil zones and vertical soil sequences (mountainous soil provinces) with similar radiation and thermal conditions (e.g., polar, subboreal, and tropical belts). In turn, these belts were subdivided into *pedobioclimatic regions* composed of horizontal soil zones and mountainous soil provinces that not only had similar radiation and thermal conditions but also similar moistening and degree of climatic continentality (e.g., the regions of boreal forests, subboreal steppes, subtropical semideserts, etc.).

The economic activity of humans is an important factor affecting microclimatic conditions. Some human impacts are directly aimed at the transformation of soil climate, i.e., soil water and temperature regimes. Thus, drainage and irrigation, shading the soil surface with a dense canopy of crops, destruction of the root mat on the soil surface by plowing, and changes in the direction and velocity of local winds caused by human constructions or artificial planting of trees (wind-breaking strips or shelter belts) lead to considerable changes in the provision of soils with heat and moisture. All these measures are aimed at maintaining the optimum parameters of soil water and heat supply during the growing season.

Climate Change: Gas Fluxes

Pascal Boeckx

Oswald Van Cleemput

Faculty of Agricultural and Applied Biological Sciences, University of Ghent, Ghent, Belgium

Abstract

Increasing concentrations of atmospheric gases, such as carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O), contribute to radiative forcing. Activities related to land use are importantly responsible for the build up of CO₂, CH₄, and N₂O in the atmosphere. A survey of techniques will be described for measuring fluxes of greenhouse gases from soils. Subsequently, sampling techniques, sample handling, and means of detection will be presented.

SAMPLING TECHNIQUES, SAMPLE HANDLING, AND ANALYSIS

Chamber Techniques

Flux chambers are simple inverted containers, which form an enclosure for gases emitted from the soil surface.^[1] Both closed (static) and open (dynamic) chambers can be used. Advantages and disadvantages of chamber techniques are listed in [Table 1](#).

Closed and Open Chambers

Emissions of carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O) are more variable, both spatially and temporally. It has not been determined whether the size of the flux chambers has an influence on this variability. Nevertheless, at least six chambers should be used per campaign. Flux chambers (cylindrical, or square or rectangular and box-like) can either be installed as a complete assembly, eventually for a short period and then removed until the next sampling occasion ([Fig. 1A](#)), or they can exist out of a basal part, which is installed for the entire duration of the experiment with a gas-tight chamber attached to it for short periods ([Fig. 1B](#)). This last variant is often used in flooded systems (e.g., paddy soils). The normal procedure for installation is to make a slit in the soil with a metal-cutting edge, the same size and shape as the collar of the chamber, and to insert the chamber collar for about 3 cm into the slit.

When a closed chamber is fixed in place, gas samples can be taken from the headspace at different time intervals. The change in concentration in the chamber over time is used to calculate the gas flux. The calculation of the flux goes through a linear regression analysis of the gas concentration increase with time (corrected for

eventual temperature changes) and a calculation of the chamber volume and area. Typical expressions of fluxes are g GHG ha⁻¹ d⁻¹. A minimum of three measurements should be made to check the linearity of concentration increase in the chamber. A non-linear increase could indicate an inadequate sealing of the chamber or an important increase of pressure in the chamber due to increase in temperature.^[2] However, venting of the closed chambers can create large errors. The chamber cover should be removed once the final sample has been taken to minimize disturbance of the environmental conditions of the area covered by the chamber.

Open chambers can be used as well ([Fig. 2](#)). In open chambers outside air flows into the chamber via an inlet and is forced to flow over the enclosed soil surface before leaving the chamber via an outlet. The concentration of the respective gas is measured at the in- and outlet sides. The gas flux from the soil surface can be calculated from the concentration difference between the in- and outlet, gas flow rate, and volume and area covered by the chamber.

Manual or Automated Sampling and Analysis

Using closed chambers, the headspace can be sampled by syringe. The gas samples are transferred to the laboratory into sealed containers (evacuated vials fitted with rubber septa) for analysis. To obtain a representative sample of the headspace, a diffusive mixing over 30 minutes is adequate, unless a mixing fan is used. Gas samples should be taken from the headspace immediately after sealing and at equal time intervals, thereafter, during which, gas concentrations increase linearly.

With automatic sampling, manual gas sampling from the chamber is replaced by a gas flow system providing a periodic sample transfer to a detector. The basic

Table 1 Advantages and disadvantages of the closed chamber, open chamber, and micrometeorological methods to measure gas fluxes from soils.

Method	Advantage	Disadvantage
Closed chamber	Simple and low cost	Labor intensive
	Multiple gases can be sampled	Small area is covered
	Small fluxes can be measured	Only a short-term emission event is monitored (1–2 hours)
	Manual and automated gas sampling can be used	Disturbance of the emitting surface upon installation
		Altered conditions of temperature and soil atmosphere exchange
		Different functioning of plants in the chamber
Open chamber	Relatively simple	Small area is covered
	Environmental condition close to uncovered field	Disturbance of the emitting surface upon installation
	Continuous long-term monitoring possible	Pressure deficits can cause artificially high fluxes
		Automated sampling is required
Micrometeorological	Useful for diurnal and seasonal variations	Expensive and sophisticated instrumentation needed
	Large areas can be monitored (aggregate flux)	Dependence on a uniform, large surface and constant atmospheric conditions
	Minimal disturbance of the emitting surface	

Fig. 1 (A) Typical closed chamber used for GHG flux measurements from aerobic soils. (B) Schematic drawing of closed chamber used for GHG flux measurements in flooded soil.
Source: (A) Adapted from IAEA^[2] and (B) Lindau, Bollich, et al.^[3]

elements of an automatic system consist of closed chambers (equipped with lids that open and close automatically) or open chambers, gas flow systems (tubing and pump); a sampling unit; an analytical unit (detector); a time controller; and a data acquisition system. Automatic sampling is more expensive and it needs to be done in the vicinity of the analysis device. However, this technique is helpful when extensive data sets need to be collected over longer periods of time. It increases the reliability of the emission data obtained, because the number of manipulations is reduced. In most cases, open chambers are sampled automatically.

Fig. 2 Field set-up of an open chamber with removable lid to measure NO fluxes from forest soils: in the front, the outlet with the air sampling tube; in the back, the air inlet with the air sampling tube and the NO analyzer with data acquisition system.

ANALYTICAL ASPECTS

Gas Chromatography

Gas samples are injected into the gas chromatograph (GC) either manually or through the use of a sample loop (automated).^[2] Depending on the type of gas to be analyzed, specific GC settings and columns are used. CO₂ is detected using a thermal conductivity detector (TCD). CH₄ is detected using a flame ionization detector. N₂O is detected using a ⁶³Ni electron capture detector (ECD). For analysis of N₂O, care must be taken to remove both CO₂ and water vapor. In experiments with acetylene, to block the last step in the denitrification process, one may need to bypass the ECD with the acetylene in the sample after it exits from the chromatographic column. Acetylene alters both the sensitivity and stability of some ECDs.

Photo-Acoustic-Infrared Detector (PAID)

The measuring principle is based on photo-acoustic detection of the absorption of infrared light.^[4] This means that any gas that absorbs infrared light of a specific wavelength can be measured. The most common PAID is the *Brüel and Kjær multigas monitor*. The PAID is equipped with a pump, which draws air from the flux chamber into an analysis cell inside the gas monitor. This cell can be sealed hermetically. Light from an infrared source is pulsed by a mechanical chopper and then passes through one of the optical filters of the filter carousel. The filter produces an infrared wavelength, which is selectively absorbed by the gas being monitored. The absorption of infrared light by the gas in the closed analysis cell causes the temperature to increase. Because the infrared light is pulsating, the gas temperature increases and decreases. In the closed cell, this results in an increase and decrease of the pressure, which can be measured via two microphones. This acoustic signal is proportional to the concentration of the gas

monitored. The *Brüel and Kjær multigas monitor* allows the analysis of five different gases and water vapor from one sample in ~120 seconds. The device has the ability to compensate for temperature fluctuations and water vapor interference. Using an automated sampling system, careful calibration of the multigas monitor and the sampling unit is required.^[4]

Micrometeorological Methods

The basic concept of micrometeorological methods for measuring trace gas fluxes to or from the soil surface is that gas transport is accomplished by the eddying motion of the atmosphere, which displaces parcels of air from one level to another.^[5,6] Transport of a gas through the free atmosphere is provided by turbulent diffusion and convection in which the displacement of individual eddies is the basic transport process. Micrometeorological methods are based on the assumption that the flux to or from the soil surface is identical to the vertical flux measured at the reference level some distance above the surface. Therefore, a flat and homogeneous terrain is needed. The flux measured at the reference level provides the average flux over the upwind area (fetch), provided that sampling point at the reference level is in the height range in which the vertical flux is constant with height (fetch ~100 H, where H = height of the sampling point). In the simplest of the micrometeorological methods, the flux may be measured by sensing the concentrations and velocities of components of the turbulence.

Two general micrometeorological techniques are used to measure trace gas fluxes: the eddy correlation and flux-gradient technique (Fig. 3). Application of both approaches is limited to situations in which the air analyzed has passed over a homogeneous exchange surface for a long distance so that profiles of gas concentration in the air are in equilibrium with the local rates of exchange. These methods also require that horizontal concentration gradients are

Fig. 3 Typical instrument for flux gradient measurements of GHG fluxes in the field.
Source: Adapted from Denmead.^[5]

negligible. Eddy correlation methods require a fast response detector. The tuneable diode laser technique is based on infrared absorption spectrometry, whereby the absorption depends upon path length, line strength, and absorber concentration. Liquid nitrogen temperature diodes are commercially available to cover the infrared spectrum from about 2 to 10 μm , the region where most trace gases have absorption spectra. Detailed information about these methods can be found by Denmead^[5] and Fowler and Duyzer.^[6] Advantages and disadvantages of micrometeorological methods are listed in Table 1.

Nonisotopic Tracer Methods

Tracer methods involve the release of an inert tracer gas, most commonly sulfur hexafluoride, from an emitting surface.^[2] The tracer gas is released at a known rate in a pattern similar to the release pattern of the greenhouse gas (GHG), perpendicular to the direction of the prevailing wind. This method can be applied when a definite plume of the GHG can be readily detected in the ambient environment. Under these conditions, the plume of the dispersed emission is located based on analyses of upwind and downwind air samples. The flux rate is computed, using the ratio of the plume concentration of the tracer and the GHG and the known release rate of the tracer. The advantage of this technique is that aggregate gas emissions can be collected from heterogeneous areas, such as landfills, circumventing the problem of spatial heterogeneity. However, the high costs, dependence on meteorological conditions, and the potential for interfering sources limit its application.

Ultra-Large Chambers with Long-Path Infrared Spectrometers

Infrared absorption spectrometers are available that can give an average value for the gas concentration over distances of tens or hundreds of meters.^[2] They are useful for

measurements of average emissions from a whole experimental plot, by covering the plot temporarily with a large canopy to act as a chamber and retain the gas emitted from the soil. The following two systems are available: 1) the Fourier transform infrared spectrometer with a mirror system, which allows multiple reflections and thus a total path of up to 1 km that is capable of measuring GHG concentration changes down to a fraction of 1 ppb and 2) a simpler, less-sensitive IR spectrometer with the capacity to detect a concentration change of about 25 ppbv of N_2O and 10 ppbv of CH_4 .

Center for the Study of Carbon Dioxide and Global Change, Tempe, Arizona, U.S.A.

Abstract

One of the most promising ways of reducing the rate of rise of the air's carbon dioxide (CO₂) content is to encourage land management policies that promote plant growth, which removes CO₂ from the atmosphere and sequesters its carbon, first in vegetative tissues and ultimately in soils. Some of these policies deal with managed forests and agroecosystems, while others apply to natural ecosystems, such as unmanaged forests and grasslands. In all instances, however, questions abound. Can carbon inputs to soils really be enhanced or carbon losses reduced? Can carbon storage in recalcitrant fractions of soil organic matter be increased, making it possible to successfully maintain new stores of sequestered carbon for long periods? And what if global warming runs wild? Will the ensuing rise in temperature stimulate plant and microbial respiration rates, returning even more CO₂ to the air than is removed by photosynthesis and leading to a negative net ecosystem exchange of carbon? These important questions rank high on the priority lists of many research organizations concerned about the planet's future climate and the sustainability of the biosphere.

INTRODUCTION

Concomitant with mankind's growing numbers and the progression of the Industrial Revolution, there has been a significant increase in the burning of fossil fuels (coal, gas, and oil) over the past 200 years, the carbon dioxide (CO₂) emissions from which have led to ever-increasing concentrations of atmospheric CO₂. This "large-scale geophysical experiment," to borrow the words of two of the phenomenon's early investigators,^[1] is still ongoing and expected to continue throughout the 21st century. Furthermore, this enriching of the air with CO₂ is looked upon with great concern, because CO₂ is an important greenhouse gas, the augmentation of which is believed by many to have the potential to produce significant global warming. Therefore, and because of perceived serious consequences, such as the melting of polar ice; rising sea levels, coastal flooding; and more frequent and intense droughts, floods, and storms,^[2] a concerted effort is underway to slow the rate at which CO₂ accumulates in the atmosphere, with the goal of stabilizing its concentration at a level that would prevent dangerous anthropogenic interference with the planet's climate system.

REMOVING CARBON FROM THE AIR

The Role of Man

There are only two ways to significantly increase the natural flux of carbon from the atmosphere to the biosphere within the time frame required for effective

ameliorative action if the ongoing rise in the air's CO₂ content is indeed a bona fide global warming threat: 1) increasing the rate of vegetative CO₂ assimilation (photosynthesis) per unit leaf area and 2) increasing the total plant population of the globe, i.e., leaf area per unit land area. Additionally, these things must be done without increasing the rate at which carbon is lost from the soil.

Man can do certain things to promote both of these phenomena while meeting the latter requirement as well. He can, e.g., increase the rate of CO₂ assimilation per unit leaf area in agroecosystems by supplying additional nutrients and water to his crops. As has been noted, however, that there are significant carbon costs associated with the production and application of fertilizers, as well as the transport of irrigation water, and factoring the CO₂ emissions of these activities into the equation often results in little net CO₂ removal from the atmosphere via these intensified agricultural interventions.^[3]

Man can also draw more CO₂ out of the air by increasing the acreage of land devoted to growing crops, but this approach simultaneously releases great stores of soil carbon built up over prior centuries. When the plow exposes buried organic matter and it is oxidized, e.g., prodigious amounts of CO₂ are produced and released to the atmosphere. But if a transition to less intensive tillage is made on fields that have a long history of conventional management and have thus been largely depleted of carbon, there is a good opportunity for nature to rebuild previously lost stores of soil organic matter.^[4]

This approach to carbon sequestration is doubly beneficial for its result in a net removal of CO₂ from the

atmosphere at the same time that it enhances a whole host of beneficial soil properties.^[4,5] Also, abandoned farmlands will gradually replenish their carbon stores, both above- and belowground, as native vegetation gradually reestablishes itself upon them. And, of course, the process can be hastened and made even more effective if trees are planted on such lands. Even without trees, it has been estimated that agricultural “best management practices” that employ conservation tillage techniques have the potential to boost the U.S. farm and rangeland soil carbon sequestration rate of 20 million metric tons of carbon per year to fully 200 million metric tons per year,^[6] which is approximately 13% of the country’s yearly carbon emissions.^[7]

Commercial forests also offer excellent opportunities for CO₂ removal from the air for considerable periods of time, especially when harvested wood is used to produce products that have long lifetimes. In addition, since some species of trees, such as many of those found in tropical rainforests,^[8] can live in excess of a thousand years, CO₂ can be removed from the atmosphere and sequestered within their tissues—if man protects the trees from logging—either until long after the age of fossil fuels has run its course or until significant changes in energy systems have reduced our dependence on fossil fuels and the CO₂ content of the air has returned to a level no longer considered problematic. Furthermore, carbon transferred to the soil beneath the trees via root exudation and turnover has the potential to remain sequestered even longer.

The Role of Nature

The fact that the biosphere has maintained itself over the eons in the face of a vast array of environmental perturbations (albeit with significant modifications) suggests that earth’s plant life has great resiliency and may even be able to exert a restraining influence on climate change.

A particularly important negative feedback of this type is the biosphere’s ability to intensify its rate of carbon sequestration in the face of rising atmospheric CO₂ concentrations, as this phenomenon slows the rate of rise of the air’s CO₂ content and thereby reduces the degree of intensification of the atmosphere’s greenhouse effect. This particular climate-moderating influence of atmospheric CO₂ enrichment was first described in quantitative terms by Idso.^[9,10] It begins when the aerial fertilization effect produced by the rising CO₂ content of the atmosphere elicits an increase in plant CO₂ assimilation rate per unit leaf area and when the concomitant plant water use-efficiency-enhancing effect of the elevated CO₂ leads to an increase in the total plant population of the globe, due to the ability of more water use-efficient plants to live and successfully reproduce in areas where it was formerly too dry for them to survive. In fact, these two effects are so powerful, they may actually be able to stabilize the CO₂ content of the atmosphere sometime during the 21st century, but only if anthropogenic CO₂ emission rates do not rise by an inordinate amount in the

interim.^[9,10] At the very least, together with the things man can do, they have the potential to “buy time” until other less-CO₂-emitting technologies become available.^[11]

KEEPING CARBON IN THE SOIL

As more carbon is added to soils via CO₂-enhanced root growth, turnover, and exudation, as well as from CO₂-induced increases in leaf litter and other decaying plant parts, the trick of significantly augmenting soil carbon sequestration is to keep at least the same percentage of this carbon in the soil as has historically been the case and to do so in the face of potential global warming.

A number of studies have addressed various aspects of this subject, with most of them finding that atmospheric CO₂ enrichment has little to no significant effect on plant litter decomposition rates. Furthermore, in nearly all of the cases where elevated CO₂ was observed to impact this phenomenon, the extra CO₂ was found to actually slow down the rate of plant decomposition.^[12] Much of the same results have been obtained when analogous studies have used temperature as the independent variable. Warming either has had no effect on CO₂ evolution from the soil or has led to an actual decrease in CO₂ loss to the atmosphere.^[13] Hence, the balance of evidence obtained from these studies suggests that the same—or a greater—percentage of plant material produced in a world of elevated atmospheric CO₂ concentration (and possibly higher mean air temperature) would indeed be retained in the soils of the terrestrial biosphere.

Even more compelling are the results of experiments where scientists have made direct measurements of changes in soil carbon storage under conditions of elevated atmospheric CO₂. Nearly every such study has observed increases in soil organic matter. In a free-air CO₂ enrichment (FACE) experiment where portions of a cotton field were exposed to a 50% increase in atmospheric CO₂, e.g., Leavitt et al.^[14] found that 10% of the organic carbon present in the soil below the CO₂-enriched plants at the conclusion of the three-year experiment came from the extra CO₂ supplied to the FACE plants. In addition, some of the stored carbon had made its way into a very recalcitrant portion of the soil organic matter that had an average soil residence time of 2200 years.

Here, too, most experiments indicate that concomitant increases in temperature do not negate the increased carbon storage produced by atmospheric CO₂ enrichment. In a two-year study of perennial ryegrass grown at ambient and twice-ambient atmospheric CO₂ concentrations, as well as ambient and ambient + 3°C temperature levels, e.g., Casella and Soussana^[15] determined that the elevated CO₂ increased soil carbon storage by 32% and 96% at low and high levels of soil nitrogen supply, respectively, “with no significant increased temperature effect.” Hence, as in the case of studies of plant decomposition rates, the balance of evidence obtained from these studies also suggests that the

same—or a greater—percentage of plant material produced in a world of elevated atmospheric CO₂ concentration (and possibly higher mean air temperature) would indeed be retained in the soils of the terrestrial biosphere.

CONCLUSION

As the air's CO₂ content continues to rise, there will almost certainly be a significant upward trend in the yearly production of terrestrial vegetative biomass, due to the growth-enhancing aerial fertilization effect of atmospheric CO₂ enrichment and the concomitant CO₂-induced increase in plant water use efficiency that enables plants to grow where it is too dry for them. Experimental evidence further suggests that at least the same percentage—but in all likelihood more—of this yearly increasing mass of plant tissue will be sequestered in earth's soils. Consequently, it is almost impossible to conclude that the carbon sequestering prowess of the planet will not be greatly enhanced in the years ahead, even without any overt actions on the part of man. Hence, if the nations of the earth were to implement even a modicum of carbon-conserving measures—such as 1) using minimum tillage techniques wherever possible in agricultural settings; 2) allowing abandoned agricultural land to revert to its natural vegetative state; 3) allowing stands of trees that can grow to very old age to actually do so; and 4) employing wise forestry practices to produce wood for making products that have long lifetimes—it is possible that the antiwarming feedback produced by the subsequent removal of CO₂ from the atmosphere would

be sufficient to keep the risk of potential greenhouse gas-induced global warming at an acceptable level. Estimates of the carbon sequestering power of some of these “best management practices” are given in Table 1.

Cobalt and Iodine

Ronald G. McLaren

Soil, Plant, and Ecological Sciences Division, Lincoln University, Canterbury, New Zealand

Abstract

Cobalt (Co) and iodine (I) are two trace elements that are generally considered to be non-essential for the growth of higher plants. However, both elements are essential nutrients for animals, particularly in the case of ruminants (sheep and cattle), and deficiencies of Co and I in grazing animals are not uncommon. Co is also essential for nitrogen fixation by microorganisms such as rhizobium and blue-green algae and can actually be toxic to plants if present at high concentrations in the soil. Most investigations into Co and I in the soil have concentrated on factors affecting the plant availability of these elements, with the aim of diagnosing potential deficiencies.

SOIL COBALT (Co)

The Co concentration in soils depends primarily on the parent materials (rocks) from which they were formed and on the degree of weathering undergone during soil development.^[1,2] Co tends to be most abundant as a substituent ion in ferromagnesian minerals and therefore has relatively high concentrations in mafic and ultramafic rocks (rocks containing high or extremely high proportions of ferromagnesian minerals). Conversely, Co concentrations are relatively low in felsic rocks (rocks containing large amounts of silica-rich minerals) such as granite and in coarse-textured quartz-rich sedimentary rocks (sandstones). Higher concentrations of Co may be associated with finer textured sediments (shales) in which Co has become surface-adsorbed by, or incorporated into, secondary layer silicates by isomorphous substitution.^[3] Typical concentrations of Co reported in different rock types are shown in [Table 1](#). As a result of the large range in Co concentrations of soil parent materials, and variation in the degree of weathering, total soil Co concentrations also vary widely. However, the mean values reported for agricultural soils from many countries appear to have a somewhat restricted range of between approximately 2 and 20 mg/kg ([Table 1](#)).

Forms of Co in Soils

Co in soils, whether released from parent materials during soil development or derived from anthropogenic contaminant sources, occurs in several different forms or associations. Co may be present as: 1) the simple Co^{2+} ion, or as complexes with various organic or inorganic ligands in the soil solution; 2) exchangeable Co^{2+} ions; 3) specifically adsorbed Co, bound to the surfaces of inorganic soil colloids [clays and oxides/hydrous oxides of aluminum (Al),

iron (Fe), and manganese (Mn)]; 4) Co complexed by soil organic colloids; 5) Co occluded by soil oxide materials; and 6) Co present within the crystal structures of primary and secondary silicate minerals.^[6] In some soils, there appears to be a particularly strong association between Co and Mn oxides, especially in soils where Mn oxides occur as distinct nodules or coatings.^[7,8]

Plant Availability of Soil Co

The immediate source of Co for plant uptake is the soil solution. However, Co concentrations in the soil solution are extremely low, generally much less than 0.1 $\mu\text{g/ml}$.^[1] Soil solution Co appears to be in equilibrium with Co adsorbed at the surfaces of soil colloids, and the distribution between solution and surface phases is strongly influenced by soil pH. As pH increases, soluble Co decreases.^[6] Similarly, soils with high capacities to adsorb Co, particularly those soils with high Mn oxide contents, also have low solution Co concentrations.^[9] Thus, in addition to soils with low total Co concentrations, the plant availability of Co may be low in soils with high pH or high Co adsorption capacities. Co availability is also influenced by soil moisture status, increasing under waterlogged conditions.^[10]

Determination of soil Co dissolved by various extractants is the most common way of assessing the plant availability of soil Co. Ideally, the forms of Co extracted should include any soluble and exchangeable Co, together with any solid-phase forms of Co that are able to move readily into the soil solution in response to changes in solution Co concentrations.^[6] The two extractants used most commonly for this purpose are 2.5% acetic acid and solutions of ethylenediaminetetraacetic acid. However, the ability of these extractants to accurately assess Co availability appears to be somewhat limited.^[11,12]

Table 1 Co and I concentrations in rocks and soils.

	Co concentration (mg/kg)	I concentration (mg/kg)
Rock type		
Ultramafic (e.g., serpentinite)	100–300	0.01–0.5
Mafic (e.g., basalt and gabbro)	30–100	0.08–50
Intermediate (e.g., diorites)	1–30	0.3–0.5
Felsic (e.g., granites and gneiss)	<1–10	0.2–0.5
Sandstones	0.3–10	0.5–1.5
Shales/argillites	11–40	2–6
Limestones	0.1–3.0	0.5–3.0
Soils		
Complete range	0.1–300	<0.1–25.4
Range of mean values	2–21.5	1.1–13.1

Co DEFICIENCY

Co deficiency in grazing sheep and cattle was first diagnosed in the 1930s, initially in New Zealand, Australia, and Scotland.^[13–15] The condition causes animals to lose their appetite, become weak and emaciated, suffer severe anemia, and eventually die. Subsequently, it was shown that Co is a constituent of both vitamin B₁₂ and a closely related coenzyme and that Co deficiency is in effect a deficiency of vitamin B₁₂.^[16] It has been concluded from field studies that pasture containing Co below 0.08 mg/kg for sheep or below 0.04 mg/kg for cattle is unlikely to meet nutritional requirements in terms of maintaining adequate serum and liver vitamin B₁₂ concentrations and healthy growth rates.^[17,18]

Co deficiency is commonly treated by applying Co-containing fertilizers to pastures, usually at very low rates, e.g., 350 g/ha/yr of CoSO₄·7H₂O. However, on some soils such treatments appear to be ineffective.^[11] Alternative treatments for Co deficiency involve injecting the animal with vitamin B₁₂, the use of Co drenches, or the insertion of slowly dissolving Co “bullets” in the animal’s rumen.

SOIL I

The range of I concentrations found in rocks and soils is shown in Table 1. I occurs as a minor constituent in various minerals, where it can replace anions such as OH[−], SiO₄^{4−}, and CO₃^{2−}, and has relatively low concentrations in most types of rock.^[19] Highest I concentrations are generally found in fine-grained sedimentary rocks (Table 1). However, soil I concentrations are generally higher than that in the rocks from which they have been derived, a fact

attributed predominantly to atmospheric accessions of I.^[20] I is known to be present in the atmosphere in vapor form and associated with particles of dust. In coastal areas, accession of I may also be related to sea spray.^[1]

Forms of I in Soils

Information of the forms of I in soils is limited, most published analyses of soils have determined total I concentrations only. Of the three most common forms of I, namely elemental I (I₂), iodide (I[−]), and iodate (IO₃[−]), it seems likely that most I in soils is present as I[−] or possibly as I₂. The presence of IO₃[−] in soils has also been postulated, but would require high oxidation conditions in neutral or alkaline soils.^[20] Indeed, there is some evidence that when IO₃[−] is added to soils, it is rapidly reduced to I₂ or I[−] by soil organic matter.^[21] There is also evidence that, under some conditions, I₂ can be volatilized from soils.^[22]

Most I in soils appears to be associated with soil organic matter and Fe and Al oxides, materials by which both I[−] and I₂ are known to be strongly adsorbed.^[21,23] Indeed, the distribution of I in soil profiles appears to follow the distribution of these soil components.^[24] The atmospheric accessions of I and the affinity between I and organic matter often result in maximum concentrations of I in the surface horizons of soils.^[20,24]

Plant Availability of Soil I

Interest in soil analysis as a means of assessing plant availability of I has been minimal,^[20] and relationships between the I status of soils and the concentrations of I in plants appear to be poor.^[1] Even soil extractants designed to determine the most soluble forms of I in soils do not provide a good indication of I availability to plants.^[25] Plants are capable of absorbing I directly from the atmosphere,^[1] and plant species or varietal differences appear to have a greater influence on plant I concentration than soil I status.^[20,26] Dicotyledonous pasture species (e.g., clovers) generally have higher I contents than do grasses.^[26] Concentrations of I in plants may be reduced by liming,^[25] by the application of nitrogen fertilizer,^[26] and by the application of farmyard manure.^[25] Seasonal effects on pasture I concentrations have also been observed, with decreases in the summer and slight increases in the autumn.^[26]

I DEFICIENCY

Low concentrations of I in food and water have been associated with the occurrence of endemic goitre (enlargement of the thyroid gland) in humans and farm livestock.^[27] Early work suggested a close relationship between goitre incidence and low soil levels of I; however, it is recognized that other factors are also involved. In particular, the

presence of a group of substances known as goitrogens, which occur in various plant species, has been shown to reduce thyroid hormone synthesis and metabolism.^[20] In the absence of goitrogens, it is considered that diets containing 0.5 mg I/kg DM will more adequately meet the I requirements of all classes of animals, while levels as low as 0.15 mg/kg might be sufficient to meet the requirements for growing animals.^[28] In the presence of goitrogens, I requirements may be as high as 2 mg I/kg DM.^[28] Attempts to increase pasture I concentrations with I-containing fertilizers have been generally ineffective, with very low recoveries of the applied I.^[25,26] Direct supplementation of livestock is normally the preferred way to increase I intakes.

CONCLUSION

Co and I deficiencies in livestock result from low soil concentrations and/or low availability of these trace elements for uptake by pasture plants. Plant availabilities of Co and I are determined by several factors including soil forms, soil sorption properties, soil pH, soil moisture status, season, plant species, and fertilizer applications. Deficiencies of Co and I can be prevented by the application of fertilizers (Co) to the soil or by direct treatment of livestock (Co and I).

Collembola

Steve P. Hopkin

Division of Zoology, School of Animal and Microbial Sciences, Reading, U.K.

Abstract

Collembola are widespread and abundant in most soils. Their biomass is low but they contribute to nutrient cycling by consuming fungal hyphae. Deposition of fecal pellets throughout the soil profile contributes to soil fertility. Collembola are beneficial, only rarely being pests of aboveground vegetation.

INTRODUCTION

Collembola (commonly known as “springtails”) are considered to be a monophyletic class of the phylum Arthropoda,^[1] although their exact taxonomic position is the subject of some debate. Many authors treat Collembola as insects. However, many of the old ideas on arthropod evolution are being reassessed in the light of modern evolutionary theory and molecular phylogeny so their placement may change.

There are three main Orders of Collembola. Members of the *Arthropleona* (about 6000 species) have a more or less elongated body shape and range from highly active surface-dwelling species to those that live out all their lives in the depths of the soil. An example of this Order is *Folsomia candida* (Fig. 1), which belongs to the Family Isotomidae. It is familiar to ecotoxicologists as one of a suite of “standard test soil organisms,” which are used to assess the toxicity of new chemicals before they are released into the environment. The *Symphyleona* (about 1000 species) have a much more rounded body shape and are mostly attractively patterned, surface-living species. A typical example is *Dicyrtomina ornata* (Fig. 2) (subfamily Dicyrtominae). The *Neelipleona* are very small soil-inhabiting springtails (typically 0.5 mm in length) with only about 25 species known in the world. They have a rounded body shape and bear a superficial resemblance to Symphyleona.

MORPHOLOGY

The oldest fossil Collembola (indeed the oldest fossil insects) are specimens preserved in Rhynie Chert of more than 400 million years in age. Collembola are present in amber in which remarkable detail is preserved (Fig. 3). The most obvious feature of Collembola is the jumping organ or furca, which is clearly visible in the specimen shown in Fig. 3 projecting behind the animal in its “sprung” state. The furca evolved through the basal fusion

of a pair of appendages on the fourth abdominal segment and is capable of propelling some springtails many times their own body length in a fraction of a second. The spring developed as an escape mechanism to avoid predators. Species of Collembola confined to the soil have a reduced furca to ease their movement between soil particles and tightly packed leaf litter. Some have lost the jumping organ altogether. The maximum number of ocelli in each eye is eight, but these are often reduced and many soil-dwelling and cave species are blind.

All Collembola have a *ventral tube* that consists of eversible sacs derived from a pair of appendages on the first abdominal segment. This organ is extremely important in fluid balance but can also function as a sticky appendage to enable springtails to adhere to slippery surfaces. In some species, the vesicles of the ventral tube may extend more than twice the length of the body and be used for self-righting after a jump. Lubbock introduced the scientific name for springtails in 1873.^[2] He rightly considered the ventral tube to be the most characteristic feature of the group and gave them the name Collembola based on the Greek *Colle* (=glue) and *embo-lon* (=piston).

Collembola are small animals. Most are only a few millimeters long although the Central European species *Tetradontophora bielensis* can reach 9 mm in length, and some members of the Subfamily Uchidanurinae grow to 10 mm and bear brightly colored “spines.” The tiniest and least-pigmented species tend to be those that live permanently in the spaces between particles of soil or sand. The blood of some Collembola possesses chemicals that act as powerful feeding deterrents to predators.^[3]

ECONOMIC IMPORTANCE

The majority of springtails feed on fungal hyphae or decaying plant material. In the soil, they may influence the growth of mycorrhizae^[4] and control fungal diseases

Fig. 1 Adults and juveniles of *F. candida*. The largest specimen is 2 mm in length.

of some plants.^[5] In general, these effects are beneficial; however, there are a few species, including *Sminthurus viridis* the “Lucerne flea,” which feed directly on plant material. In Australia, a country to which *S. viridis* has been introduced, the species can cause significant economic damage.^[6] Some springtails are carnivorous and eat nematodes, rotifers, and even other Collembola.

LONGEVITY

Springtails are generally short-lived. Few survive as adults for more than a year or two. The documented longevity record is held by *Pseudosinella decipiens*, which survived for up to 67 months in the laboratory, although some cave species, or those in very cold climates, may live longer. Most Collembola continue to moult after reaching reproductive maturity and may alternate reproductive and “sexually dormant” instars through several cycles. Several species are parthenogenetic (males absent) including *F. candida* (Fig. 1).

HOW MANY SPECIES?

Approximately 7000 species of Collembola have been described although it is difficult to give an exact figure as there are many species yet to be discovered, especially in countries such as Australia and New Zealand where there is a high level of endemism. The estimate of the total number of species of all insects on the earth quotes a figure of between 5 and 10 million, less than 20% of which have been described.^[7] In view of their cryptic behavior and relative lack of scientific study, it is likely that at least 50,000 species of springtail exist on our planet.

DISTRIBUTION

Collembola have a very wide global distribution. They are abundant on every continent, including Antarctica, where *Biscoia sudpolaris* and *Antarctophorus sudpolaris* have been found crawling among lichen at a latitude of 84°47'S, the most southerly location for any invertebrate.^[8] *Aackia karakoramensis* occurs on newly fallen snow in the Himalayas at an altitude of 7742 meters.^[9] *Folsomides arnoldi* is abundant in Australian deserts.^[10]

Collembola are common on the seashore. *Anurida maritima* is a marine species and is one of the most familiar invertebrates of the littoral zone in Europe.^[11] Several species live almost permanently on the surface of freshwater, including the common and widespread *Podura aquatica*, a frequent sight on puddles after rain, sometimes in huge numbers. Species of *Hypogastrura* are abundant and are important in clearing growths from the percolation filters of sewage beds.

Many species live all their lives in the soil, where they penetrate more than 150 cm below the surface. Others live on trees and are abundant in rain forest canopies. In one

study, about one million Collembola of 16 species were collected from 100 m² of dry forest in Mexico by insecticide fogging.^[12] Some Collembola are specialized for living in sand.^[13]

DIVERSITY

Habitats with extreme climates such as deserts and polar regions support few species of Collembola, but sites with many niches have a diverse springtail fauna. Collembola seem to follow the general rule that diversity is inversely related to latitude; that is, there are more species in tropical than in temperate zones. In tropical rain forests, more than 130 species/m² have been found in soil, leaf litter, and aboveground vegetation.^[14] In more temperate forests, diversity is lower, but it is not unusual to find more than 40 species in deciduous woodland.^[15] Collembola exhibit dominance patterns typical of most groups of terrestrial arthropods. The majority of individuals are usually represented by a small number of common species. In most populations, a large fraction of the species (usually >50%) is rare with dominance values of <1%.

“SWARMING”

Collembola are most obvious when they swarm. Most reports are of species in the family Hypogastruridae. They occur following synchronized reproduction in conditions of ideal humidity and temperature and abundant food supply. There are numerous references in the literature to swarming, particularly on snow and glaciers (e.g., Hagvar^[16]). Swarms certainly can be huge, often comprising several millions of individuals. The reasons for this behavior are not completely understood, although in most cases the Collembola are probably searching for a more favorable habitat after becoming overcrowded.

ABUNDANCE

Collembola are extremely abundant in soil and leaf litter. In most terrestrial ecosystems, they occur in high numbers, typically between 10⁴ and 10⁵/m². Densities of springtails of more than 10⁵/m² have been found in pine forests in India and Japan, moorland in England, and dry meadows in Norway. Collembola are particularly abundant in agricultural soils that are farmed “organically.”^[17] In the rain forests of Seram, Indonesia, Collembola comprise about 20% of the total number of arthropods on tree trunks and 50% and 60% of the total from soil and leaf litter, respectively.^[18] However, because of their small size the contribution of Collembola to total soil animal biomass and respiration is low, typically between 1% and 5% in temperate ecosystems, but up to about 10% in some arctic sites

and as much as 33% of total soil fauna respiration in ecosystems in the early stages of succession. Typical values for the dry weight of springtails in temperate ecosystems are 0.15 g/m² in deciduous woodland and 0.3 g/m² in limestone grassland.

EFFECTS ON SOIL STRUCTURE

Despite their relatively low biomass, springtails are extremely important in influencing the structure of some soils. For example, “alpine pitch Rendzinas” on limestone are composed mainly of a deep black humus layer of 15–20 cm in depth that is formed almost entirely of Collembola feces.^[19] Most soils contain millions of collembolan fecal pellets/m², and these must be beneficial in slowly releasing essential nutrients to plant roots as the pellets are broken down by microbes.

ROLE IN DECOMPOSITION

The main effect of Collembola on decomposition and “soil respiration” is through feeding on fungal hyphae. At certain densities of Collembola, grazing of mycorrhizae on roots can stimulate growth of the symbiont and improve plant growth.^[4] In other situations, Collembola may reduce disease by consuming pest fungi.^[5]

Selective grazing by springtails may be an important factor limiting the distribution of certain species of basidiomycete fungi in the field. However, many of these effects are density-dependent, and too little information is available for quantifying accurately the specific contribution of Collembola to “indirect” or “catalytic” decomposition. Nevertheless, the influence of springtails on decomposition and nutrient availability must be significant in many ecosystems.

CONCLUSION

Collembola are widespread and abundant in most soils. Their biomass is low but they contribute to nutrient cycling by consuming fungal hyphae. Deposition of fecal pellets throughout the soil profile contributes to soil fertility. Collembola are beneficial, only rarely being pests of aboveground vegetation.

Further Reading

Further information can be found in the review by Hopkin, which contains a list of the most important references on Collembola published before 1996. A list of Collembola publications from 1995 onward is available at <http://www.stevehopkin.co.uk/collembolapapers/>. A very detailed Collembola site is maintained by Frans Janssens at <http://www.collembola.org>. This includes a

world checklist of species together with identification keys to genus level for most families. Since the publication of Hopkin a number of important reviews have been published that should be consulted for developments in taxonomy, ecotoxicology and general biology. These are as follow:

- a major revision of the Iberian Collembola by Jordana et al.
- a second edition of the key to North American Collembola by Christiansen and Bellinger
- the first volume of a key to the Nordic Collembola by Fjellberg
- three volumes in the series on Palaearctic Collembola
- a review of developments in Collembola taxonomy
- a discussion of the use of 'standard' springtail *F. candida* in laboratory experiments.

Color

Robin N. Thwaites

*School of Natural Resource Sciences, Queensland University of Technology,
Brisbane, Queensland, Australia*

Abstract

Soil color, defined through a standard system, plays an important role in all major soil classification systems and for all means of soil interpretation. Although soil color per se has no known direct effect on soil behavior (except for heat absorption at the surface), it provides a valuable indication of soil conditions, composition, and genesis. It can indicate the conditions of aeration (therefore drainage), organic matter content, fertility, and degree of weathering. Color is also a major criterion to differentiate horizons within a soil as a means to its classification and interpretation.

INTRODUCTION

Soil color is one of the most evident characteristics observed on viewing a soil exposure. It is often used in lay terms as a descriptor for any soil type, e.g., “red soils,” “black soil,” and “mottled soils,” and it is always recorded as part of a soil description for inventory purposes. The pioneering Russian school of pedology noted variations in soil color before the turn of the 19th century, but it was not until the end of the 1920s before a satisfactory attempt had been made in the United States to standardize colors of dry soil samples.^[1] Soil color, defined through a standard system, plays an important role in all major soil classification systems and for all means of soil interpretation. Although soil color per se has no known direct effect on soil behavior (except for heat absorption at the surface), it provides a valuable indication of soil conditions, composition and genesis. It can indicate the conditions of aeration (therefore drainage), organic matter content, fertility, and degree of weathering. Various minerals at different stages of weathering, particularly the iron (Fe) oxides, lend their color to the soil matrix and to individual soil grains. Color is also a major criterion to differentiate horizons within a soil as a means to its classification and interpretation. It can occur as whole-colored matrix of the soil, as mottles (blotches and specks), in marbled or streaked patterns, as precipitates around mineral grains (lining root holes), or as nodules and other segregations.

MEASURING SOIL COLOR

Soil colors vary from very pale blues and greens and grays, even white, through browns, yellows, oranges, and reds, to dark forms of these as well as completely black. There is a general perception that soil color cannot be measured with any precision or accuracy, but color has been recorded

consistently and assiduously in both the field and the laboratory for many years. The routine determination of soil color in the field is the less precise and less accurate form of measurement, although consistent results can be achieved with experience. It is determined through visual comparison of a small, fresh soil sample with color chips in standard color charts. The most familiar and widely used are the Munsell Soil Color Charts.^[2] The Munsell color scheme is an objective three-coordinate system that defines color through its *hue* (shade), *value* (lightness), and *chroma* (intensity/saturation; Fig. 1). For soil colors, the Munsell chart ranges in value from 0 to 10, in chroma from 0 to 8, and in hue (in units of principal colors—which are primarily red and yellow for soils) as 10R (red), 2.5YR (yellow–red), 5YR, 7.5YR, 10YR, 2.5Y (yellow), and 5Y. Red soil colors are usually 5YR or redder (with chromas >1), and yellow soils are hues 7.5YR or yellower. Dark soil colors have values <3 and chromas <2 for any hue. Some soil colors have been recorded outside this standard range (e.g., 5R in Central Australia), but these occurrences are rare. Some “gley” hues (5Y, 5GY, 5G, 5BG, and 5B) are also included in the standard charts to account for pale yellow, green, and blue colors from hydromorphic, or waterlogged, soils with reduced ferrous Fe conditions. Color matching is usually undertaken on moist, or moistened, soil samples, although dry soil colors are needed for some classification purposes. Moistening a soil can darken the value by up to three units and up to two units in chroma.^[3]

Soil colors measured this way rarely match with the standard color system perfectly, and training is recommended to perform consistent and accurate color matching.^[4] The factors that most affect visual perception of soil color are as follows: 1) the light source characteristics illuminating the sample; 2) the surface characteristics of the sample; and 3) the variable spectral response characteristics of the human eye.^[5] Even among professional soil scientists agreement on the same color “chip” in the

Fig. 1 The Munsell 3-D color concept. The hue and chroma ranges for a value of five are shown. Thus, the pointed arrow represents a color of 10YR 5/6.

Munsell chart for all three-color components is around 50% for a variety of soil color samples, although this rises to around 70% for individual color components.^[4]

In the laboratory, soil color can be ascertained best by spectral reflectance from prepared, disturbed soil samples via a diffuse reflectance spectrophotometer. The reflectance data provided by this process can be converted to a three-figure “tristimulus” value that defines the visually perceived color. This, in turn, can then be converted to a standard color system such as the Munsell notation.^[6] Photoelectric colorimeters can also be used, but results are deemed to be less accurate.^[6]

WHAT CAUSES SOIL COLORS?

Variations in soil color may be due to soil forming processes or inherited from the parent material. It was

recognized in the earliest known study devoted to soil color in 1911^[7] that the color of soil depends on the content of organic matter and the type of Fe oxides. Several Fe oxide mineral types can be present in soil, and they each possess distinctive colors (Table 1).^[8] The type of Fe mineral present is influenced by the parent material and the immediate soil environment. The type and amount of organic matter will influence the darkness of the topsoil. It must also be realized that some soil colors may be relics from prior climates and landscape processes that do not affect the soil.

There is a broad relationship between the darker color of surface soils and organic matter content. However, the relative darkness does not reflect absolute levels of organic matter content. Higher levels of humification will produce darker colors as it will increase wetness: The near black color of some peats and mucks is due to intense humification. The dark color of many black soils (e.g., dark clays with high calcium carbonate contents) may not be attributable to high levels of organic matter but rather due to the clay mineralogy and stage of humification.^[9] The nature of the organic compounds will usually be clay–Fe–(manganese)–organic matter complexes. Intense black coloration, often as mottles, is due to the presence of manganese oxides.

The bright brown, red, and yellow colors of many subsoils are caused by oxidized (often hydrated) Fe products, Fe(III) oxides (or “Fe oxides”), in the fine clay-sized fraction. Contrary to common belief, it is not the *amount* of Fe oxides in the soil that determines the nature of the color but the *type* and *nature* of Fe oxides. The Fe mineral responsible for most non-organic soil coloration is goethite (α -FeO–OH), which imparts colors from reddish-brown through brown to yellow with increasing hydration. Goethite, the most common soil Fe oxide, gives Munsell hues of 10YR–7.5YR if it is finely dispersed; variations in this color come from variations in crystal size and cementation.^[8] The cementation of goethite into nodules and ferricretes darkens the appearance. The strong red colors of tropical and subtropical soils under aerobic conditions are due to the dominance of hematite (α -Fe₂O₃). This mineral

Table 1 The soil colors and soil environments associated with the common Fe oxides.

Fe oxide: formula	Munsell color range	Soil environment
Goethite: α -FeOOH	7.5YR–2.5YR (brown–reddish yellow–reddish brown–dark red)	Weathering of all soils in all regions with Fe release
Lepidocrocite: γ -FeOOH	5YR–7.5YR, value ≥ 6 (light brown–reddish yellow–light reddish brown–pink)	Non-calcareous, aerobic/anaerobic conditions in temperate regions
Hematite: α -Fe ₂ O ₃	7.5YR–5YR (brown–reddish yellow–yellowish red–reddish brown)	Aerobic conditions of the tropics and subtropics. High Fe release rate, high soil temperature, rapid biomass turnover, low leaching activity
Maghemite: γ -Fe ₂ O ₃	2.5YR–5YR (red–reddish brown–reddish yellow–yellowish red)	Tropical and subtropical regions. May be a product of fires
Ferrihydrite: Fe ₅ HO ₈ · 4H ₂ O	5YR–7.5YR, value ≤ 6 (reddish brown–yellowish red–brown–dark brown)	Rapid oxidation in humic environments in gleys and Podzols (Spodosols)

Source: Adapted from Schwertmann.^[8]

gives Munsell hues of 5YR–5R, but, again, variations are due to crystal size: larger hematites, in the micrometer range, tend to purple colors and may even reach Munsell RP hue.^[8] Other Fe oxides that may impart distinctive colors to the soil are as follows: 1) lepidocrocite (γ -FeO–OH), which gives dull yellow to orange mottle colors in anaerobic/aerobic, gleyed conditions; 2) ferrihydrite ($\text{Fe}_5\text{HO}_8 \cdot 4\text{H}_2\text{O}$) giving rusty red colors to specks, mottles, and root holes in otherwise wet or waterlogged (anaerobic) conditions, including the reddish tinge to the Podzol (spodic) B horizon (Bs and Bhs); and 3) maghemite (γ -Fe₂O₃), often the result of fire affecting the soil transforming goethite, produces colors between those of goethite and hematite.^[8]

Other Fe compounds impart distinctive colors to subsoils. A special case is that of jarosite [$\text{KFe}_3(\text{OH})_6(\text{SO}_4)_2$] which occurs commonly as yellow (5Y) mottles in acid sulfate soils. Reduced Fe compounds (through anaerobic, often waterlogged, conditions) lack the red and yellow pigmentation. The soil matrix under these conditions attains a range of shades between gray, green, and blue, as the Fe oxides are completely removed after mobilization by microbial reduction. These “gley” colors form in ferriferrous clay minerals through partial reduction of structural Fe.^[8] It is possible that some of the greenish tinge is also due to the presence of the so-called “green rusts,” which are a group of Fe(II, III) hydroxy salts. If this is the case, then the minerals lose their color rapidly upon exposure to air.^[8]

In some cases, subsoil colors may be inherited from distinctively colored parent materials, e.g., red–brown soils from hematite-rich red sandstone, green tinges from glauconite-rich substrates, red soils from pre-weathered volcanic ash deposits, and sooty black soils from manganese-rich, ore-bearing substrates.

SOIL CONDITIONS INDICATED BY COLOR

Dark brown colors near the surface are associated with high levels of organic matter, thus higher than average nutrient fertility.

Bright yellows and reddish colors in the subsoil signal the presence of Fe(III) oxides, therefore indicating good drainage and aeration conditions. Red soils are usually better aerated/drained than yellow soils. The strong surface charge of these Fe oxides also contributes to the good aggregation properties of the soil.^[9]

Very pale gray to white colors, particularly in earthy fabric topsoils, indicate significant leaching and low organic matter. Fertility status is, therefore, low. A distinctively paler sub-topsoil horizon, characterized by leaching, is known as an E (eluviated), or A₂, horizon and is distinctive in Podzols (Spodosols).

Orange or dull yellow mottles (lepidocrocite) in gray, bluish, or greenish (reduced) ferriferrous clay matrix (gley) signify prolonged anaerobic conditions, permanent or seasonal waterlogging.

Table 2 Simple indications given by some soil color characteristics and examples of possible soil types, for illustrative purposes only.

Color characteristic	Indication	Soil type example
Brown, whole-colored profile	Well drained, moderately weathered, high organic matter, high fertility	ST: Haplustoll; FAO: Chernozem
Red, whole-colored profile	Well drained, highly leached, intensely weathered (high proportion of sesquioxides), low fertility	ST: Durargid, Humox; FAO: Ferralsol
Yellow, whole-colored profile	Moderately drained, moderately leached, moderately weathered (goethite dominant), moderate fertility	ST: Haplustalf, Paleustult; FAO: Xanthic Ferralsol, Ferric Luvisol
Black, whole-colored profile	Moderately to imperfectly drained, little weathered, little leached, high organic carbon, high fertility	ST: Ustert, Haploxeroll; FAO: Pellic Vertisol, Rendzina
Black topsoil, whole-colored	Imperfectly to poorly drained, high organic matter, unweathered, unleached, high fertility	ST: Umbrept; FAO: Humic Cambisol, Humic Podzol
Gray topsoil, whole-colored	Well drained, leached, low organic carbon, low fertility	ST: Palexeralf; FAO: Dystric Cambisol
Pale-white subsoil	Intensely leached, no organic carbon and low cations, very low fertility	ST: Haplorthod; FAO: Podzol, Albic Luvisol
Yellow subsoil, whole-colored	Moderately drained, moderately weathered, high Fe content (probably goethite), moderate fertility	ST: Paleustalfs; FAO: Luvisol, Acrisol
Green–gray mottled subsoil, Green–blue mottled subsoil	Poorly drained, often saturated by groundwater, anaerobic/reducing conditions (Fe(II) oxides), poor fertility	ST: Aquult; FAO: Gleyic Acrisol, Gleysol
Red–yellow mottled subsoil	Imperfectly drained, fluctuating water status (may be relict), regular oxidizing of wet soils (Fe(III) oxides), mod-poor fertility	ST: Paleustult, Palexeralf; FAO: Plinthic Luvisol, Chromic Luvisol
Orange–rusty mottled topsoil	Regular surface waterlogging and draining of surface, oxidizing mineral matter, high organic matter, mod-high fertility	ST: Pellustert; FAO: Chromic Vertisol

Note: ST, soil taxonomy; FAO, FAO/UNESCO soil map of the world.

Black matrix material or mottles in wet conditions with a hydrogen sulfide (rotten eggs) odor (the anaerobic decay of organic matter) indicate severe permanent waterlogging to the surface (either perched or from groundwater).^[9]

Red, orange, and yellow mottles in pale (sometimes colored) matrix, often in a marbled pattern, may well be relict features of previous weathering environments associated with fluctuating water tables. Such features are common to the so-called “lateritized” soil profiles on older geomorphic surfaces where existing weathering environments are not responsible for the observed, dominant color patterns.

Other indications are given in [Table 2](#).

Compaction

William E. Wolfe

Department of Civil and Environmental Engineering and Geodetic Sciences, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Compaction is perhaps the oldest technique for enhancing the engineering properties of a soil mass. Experience in compacting a large number of soil types has shown that, in many soils, adequate engineering properties can be expected, if a minimum density that can be related to the laboratory Proctor density is achieved. This knowledge allows the geotechnical engineer to reduce the testing that must be done to establish the performance of compacted soil profiles.

INTRODUCTION

A determination of the behavior of a soil mass subjected to structural loads is performed by a geotechnical engineer who evaluates soil properties and makes design recommendations. Satisfactory performance is usually achieved when ground movements are small enough that the structure placed on the prepared soil behaves the way the owners want it to. This is accomplished by specifying minimum performance requirements. Often, on-site soils are not ideally suited for the proposed project, and the specified performance cannot be achieved unless the soil's properties are modified.

Modification can be accomplished in a number of ways. The two most commonly used classes of modification are chemical stabilization and mechanical stabilization. Chemical methods involve the addition of a stabilizing agent, usually lime or cement, to the soil. The chemically modified soil has a higher strength and lower compressibility than the untreated soil. Chemical additives have also been effective in reducing the swelling potential in clays. A mechanically modified soil has had its properties improved either by the inclusion of foreign material (usually reinforcing elements) or by densification. Densification is most commonly achieved through preloading or compaction. The two methods differ in the means employed to achieve the necessary increase in density. Preloading is used primarily to force water out of a saturated soil. Because preloading causes a reduction in volume by forcing water to flow away from areas of load, preloading a site requires the imposition of large loads over extended periods of time. The principles governing the rate and quantity of volume decrease accomplished by preloading are discussed in the section on consolidation.

In the compaction process, the volume of void space is reduced by applying high loads over small areas to force the

air out of an unsaturated soil mass. Because the area covered by the compaction load is much smaller than the one used to preload a site, the volume of soil stabilized during each application of the compaction load is much less. So, to be successful, the treatment must be moved from place to place and applied to thin layers. The most common method involves driving heavy vehicles, a specified number of times (passes) over the soil surface, as the soil is being placed. Typically, each 8–12 in. (20–30 cm) thick layer of the soil is compacted and the amount of compaction measured. Since the procedure specifically targets the air fraction of the soil mass, the water content is not affected by compaction.^[1]

COMPACTION PRINCIPLES

Although compaction may not change the water content of a soil, the maximum density obtainable does depend on the amount of water present in the soil mass. Although the engineering properties of all soils are affected by the soil density, the response of a coarse-grained soil to compaction is different and needs to be considered separately from the response of a fine-grained soil.

Coarse-grained soil—because the individual particles in a coarse-grained soil are chemically inert, there is little interaction between the solid and liquid fractions of the soil mass. The effect of water in the deposit is largely through the formation of capillary tensions, which result in the particles being tightly bound in a matrix that resists rearrangement. As the degree of saturation increases, the capillary forces are destroyed, and compaction energy becomes more effective in densifying the soil. An example of a compaction curve obtained for a coarse-grained soil is presented as [Fig. 1](#). Vibratory loading has been found to be the most effective method for densifying coarse-grained soils.^[2,3]

Fig. 1 Typical compaction curve for a coarse-grained soil.

Fine-grained soil—compaction tests performed on fine-grained soil samples have clearly shown that for every soil and compactive effort, an optimum water content yielding the greatest density of the solid fraction (dry density) can be identified. At water contents both above and below the optimum, the same compactive effort results in lower soil densities. Typical curves showing the dependence of density on water content and compactive effort are presented in Fig. 2.

Although the density decreases above and below the optimum water content, the behavior of the soil is much different on the two sides of the optimum condition. On the dry side of optimum, the electrical charges on the sheet-like solid particles encourage an edge to face orientation of the individual soil grains with the resultant structure looking something like a honeycomb. This particle arrangement results in a fairly open structure, but one in which the high negative pressures in the water resulting from capillary tension cause the individual particles to be tightly bound together. As water content increases, the capillary tensions decrease. This decrease in capillarity reduces the force holding grains together and increases the effectiveness of the compactive energy. The particles are forced into more orderly patterns. As the water content continues to increase, the air volume fraction becomes small enough that air voids are discontinuous and so air cannot be easily expelled. The maximum density is quickly reached, and further increases in water content merely increase the water adsorbed onto the solid grains reducing contact strength and density.^[3]

TESTING

It is the job of the geotechnical engineer to determine if the soil, whether on-site or imported, is strong or stiff enough to support the design loads. The most direct measure of the ability of a soil to perform as designed would be to measure the strength, stiffness, and/or hydraulic conductivity at many locations in the field. In most cases, field testing of these important engineering properties is not practical, and an indirect measure of how the soil will behave when loaded is appropriate.

Fig. 2 Typical compaction curves for a fine-grained soil.

Density and moisture content are the most common substitutes for the actual soil properties upon which design was based.

Laboratory Tests

The actual combination of maximum dry density and optimum moisture content is different for each soil. Therefore, a laboratory obtained moisture content vs. density relationship such as one of those shown in Fig. 2 should be developed for each different soil or mixture of soils to be used on the site. A moisture-density curve is generated by plotting the results of five separate compaction tests performed on different samples of the same soil at five different moisture contents. Several test methods have been standardized by the American Society for Testing and Materials (ASTM).^[4] The most commonly used are referred to as the Standard Proctor Test (ASTM D-698) and the Modified Proctor Test (ASTM D-1557), after R.R. Proctor, who developed the procedures for conducting repeatable compaction tests in the 1920s and 1930s.

Ideally, the engineer then performs the appropriate engineering tests on laboratory samples compacted to the optimum moisture content and density. Once the data showing a correlation between soil density and its strength and stiffness have been generated for each soil type, the density and water content become surrogates for the true design parameters. Because these two parameters are easy to determine and can be related to the significant engineering properties, the measurement of density and moisture content has become the preferred method for verifying adequate preparation of the soil.

Field Tests

With the laboratory data obtained as described above, field verification of the appropriate density and moisture content is the extent of the field testing necessary to be confident that the required strength and stiffness have been achieved. The two methods most commonly used to check density are the sand cone method (ASTM D-1556) and the nuclear gauge (ASTM D-2922).

Fig. 3 Troxler Model 3450 moisture/density gauge in the direct transmission mode.

Sand Cone

In this method, a test hole is excavated in the soil whose density is to be determined and all the excavated material weighed. The hole is filled with a clean, uniform sand of a known density, and the amount of sand used to fill the hole is determined. A fraction of the sample of the soil from the hole is dried in an oven at 105°C to determine the water content. The field density and water content can then be compared with the optimum conditions obtained in the laboratory.

Nuclear Gauge

The principle behind the use of the nuclear gauge is that measuring the attenuation of gamma radiation can accurately determine the total density and water content of a near surface soil. In the direct transmission method, a radiation source is placed in a predrilled hole, usually about 300 mm below the surface. A gamma radiation detector is placed on the ground surface. In the backscatter method, both the radiation source and the detector are

placed on the ground surface.^[5] Fig. 3 depicts a nuclear gauge (Troxler Model 3450) measuring the density of clay material in the direct transmission mode. The nuclear gauge has become a very popular way to make density and water content determinations because it is much faster than other methods, less prone to operator error and, in the backscatter mode, is non-destructive, since no excavation needs to be made. However, since the method is an indirect measure of density, the instrument must be calibrated at the start of each day's work, and the calibration must be kept in the permanent record for the gauge. In addition, the precision of even properly calibrated gauges may be adversely affected by a number of elements in the soil including organic matter. The U.S. Army Corps of Engineers^[6] specifies that readings from a nuclear gauge must be frequently compared with direct measurements for density (sand cone) and water content (conventional oven).

CONCLUSION

Compaction is perhaps the oldest technique for enhancing the engineering properties of a soil mass. Experience in compacting a large number of soil types has shown that, in many soils, adequate engineering properties can be expected, if a minimum density that can be related to the laboratory Proctor density is achieved. This knowledge allows the geotechnical engineer to reduce the testing that must be done to establish the performance of compacted soil profiles.

Abstract

Soils are a critical natural resource for the future development and sustainability of humankind. Natural resource assessment tools are often used to evaluate the effects of management on soil properties and processes to ensure the sustainable use of our limited soil resources. The soil conditioning index (SCI) is a soil assessment tool used to predict the consequences of management actions on the state of soil organic matter. Although SCI is correlated with particulate (labile) organic matter and residue returned to the soil, it is not a precise index. Calculated SCI values may vary by about ± 0.2 to ± 0.3 . This entry describes the use, determination, and evaluation of the SCI on agricultural lands in the United States.

INTRODUCTION

Soils are a critical natural resource for the future development and sustainability of humankind. Not only soils are used to produce our food and fiber, but also they serve as critical environmental filters for waste treatment and recycling and act as important sources and sinks for nutrients, gases, and other materials essential for proper functioning of life processes. Natural resource assessment tools are often used to evaluate the effects of management on soil properties and processes to ensure the sustainable use of our limited soil resources.

SOIL ORGANIC MATTER (SOM)

SOM is an important constituent in the soil surface and provides several important functions. Strictly speaking, organic matter is any material derived from living organisms. Organic matter in soil also originates from biological material and is composed chiefly of molecules containing carbon (C) from plants and a variety of other soil organisms such as arthropods, microbes, and others. As these living organisms die and decompose, they are transformed by biological, physical, and chemical processes into decomposed organic matter called humus. SOM is important in the formation of stable soil structure that resists wind- and water-induced erosion and promotes increased water infiltration into the soil. SOM improves soil fertility and acts as

a reservoir for soil nutrients by increasing the soil's ability to absorb and hold nutrients and water. SOM is a primary indicator of soil quality and an important factor in C sequestration and global climate change. Knowledge of how land management changes SOM is critical to understand how management affects important soil properties and functions.

SOIL CONDITIONING INDEX (SCI)

The SCI is a soil assessment tool used to predict the consequences of management actions on the state of SOM. The Natural Resources Conservation Service (NRCS), part of the U.S. Department of Agriculture (USDA) has adopted the SCI to evaluate cropland management systems in the United States. The SCI is a dimensionless index that predicts qualitative changes (positive or negative) in SOM in the top 10 cm (4 in.) of soil based on the combined effects of three dimensionless determinants of SOM using the following equation:

$$SCI = (OM \times 0.4) + (FO \times 0.4) + (ER \times 0.2) \quad (1)$$

where OM is the organic material (biomass) from animal or plant sources produced and returned to the soil, FO represents field operations including tillage and other cultural practices that stimulate organic matter breakdown and decomposition, and ER corresponds to the influences of wind and water erosion.^[1] Both OM and FO each account

Fig. 1 The SCI considers OM input, field operations and other soil disturbance, and wind and water erosion.

for 40% of the final SCI value (total of 80% combined), and wind and water erosion represent 20% (Fig. 1). The SCI assumes that field operations reduce SOM by stimulating decomposition and that maintaining organic residues with no or very limited tillage will maintain and increase soil organic levels.

THE USE OF SCI

The SCI is an important soil management index and is required by several USDA–NRCS soil or crop management guidelines, including the Conservation Crop Rotation guideline, and as an additional criterion in the Residue and Tillage Management—No Till/Strip Till/Direct Seed guidelines, and is specified for use in the Conservation Security Program of the Farm Security and Rural Investment Act of 2002. The USDA–NRCS uses SCI to develop sustainable conservation plans at the field, watershed, and larger scales.

DEVELOPMENT OF THE SCI

The SCI was originally developed based on research conducted from 1948 to 1959 in a humid region with high clay soils at Renner, Dallas, Texas, U.S.A. The SCI was first published in 1964 as a soil rating system for soils of the Western United States as USDA Conservation Agronomy Technical Note No. 27. This note was revised in 1967 and 1974, and a shorter version of this rating system was later prepared for use by the USDA Soil Conservation Service, Southern National Technical Center.^[2] Further modification of the concept was provided using data from Iowa and Montana.^[1,2] The USDA Soil Quality Institute made final adjustments to determine the amount of residue needed to maintain SOM at constant levels in 2000. The SCI was incorporated into the Revised Universal Soil Loss Equation

(RUSLE2), a computer model to estimate water erosion on cropland, in 2003.^[1]

The SCI value is usually determined by applying Eq. 1 to specific field locations using RUSLE2, which uses information on the local climate, soils, crop, and tillage to estimate annual water erosion and the SCI value. Since wind and water erosion are both included in the ER subfactor of Eq. 1, wind erosion may also need to be determined if it occurs. However, wind erosion is not determined by RUSLE2 and must be provided by another method. Wind erosion is estimated using an MS Excel spreadsheet program,^[3] based on the USDA Wind Erosion Equation (WEQ). Where it is a factor, the estimated wind erosion total is manually entered into RUSLE2 before making the final determination of SCI.

SCI TESTING

The SCI was tested by USDA–NRCS staff scientists using data from 36 long-term crop production research sites to determine how well it could detect the trend in organic matter content. This study showed that SCI could identify the general trend in organic matter accumulation or depletion in 97% of the tests. Fig. 2 shows how the SCI varied with the annual amount of change in organic matter for each test. When the SCI was less than 0, the annual change in SOM was negative. The annual change in SOM was positive when the SCI was greater than 0. Another evaluation of SCI using nine long-term cropping studies also found that positive trends in SOM followed positive trends in SCI, and negative SCI trends were associated with negative SOM trends.^[4] Correlations between SOM and SCI were improved when data were separated by states.

A test of SCI on 52 fields in the Southern High Plains of western Texas successfully associated the conservation grasslands, native rangelands, and no-tillage, limited (minimum) tillage, and high-residue croplands with positive SCI values and the conventionally tilled fields with negative SCI values.^[5] The conservation grasslands had the

Fig. 2 Comparison of SCI with percent annual change in organic matter for 36 long-term tillage study sites.

Fig. 3 SCI by agroecosystem. CT = conventional tillage, NT = no tillage, LT = limited tillage. Error bars are standard errors.

highest SCI value, and the conventionally tilled dryland cotton had the most negative SCI value. The SCI values by agroecosystem tested are shown in Fig. 3. Rather, subtle changes in soil management were detected by using RUSLE2 and a spreadsheet version of the WEQ to determine the SCI.^[5] Although the stated purpose of the SCI is to predict the consequences of management actions on the state of SOM, the SCI values were not strongly correlated with total SOM. The SCI values were more strongly associated with a specific and more labile form of soil organic C called particulate organic matter C. The SCI was even more strongly correlated with a measure of residue production, which serves to add organic matter to the soil and protect the soil from the forces of erosion. This study suggests that although SCI is a good estimate of organic matter, it is not a precise index. It may be advisable to have a buffer of ± 0.2 or ± 0.3 when assigning SCI values. This buffer may be particularly necessary in Western states where the OM subfactor in SCI may often be less than 0, even in situations with adequate cover.

A more comprehensive soil quality assessment tool evaluating biological, chemical, and physical indicators is offered by the Soil Management Assessment Framework (SMAF). This tool provides a consistent approach for evaluating and, if desired, combining various soil biological, chemical, and physical indicator measurements for an overall assessment of dynamic soil quality.^[6] The SMAF was used to synthesize information from cropping system comparisons throughout the U.S. Great Plains.^[7]

CONCLUSION

The SCI is a soil assessment tool used to predict the consequences of management actions on SOM trends. The SCI is determined using wind and water erosion models. The information needed to run the models includes field location, type of crops grown, yields, tillage, and other management information. Much of the information needed to run the models is available in public databases. Although

SCI is correlated with particulate (labile) organic matter and residue returned to the soil, it is not a precise index. Calculated SCI values may vary about ± 0.2 to ± 0.3 .

Abstract

Soil erosion is a natural process that has been a major problem for all civilizations since recorded time began. Conservation tillage or crop residue management systems range from no-till or direct-seeding methods to reduced tillage systems that disturb the soil but leave the required amount of crop residue on the soil surface after planting. Conservation tillage can greatly reduce water- and wind-driven soil erosion. In spite of its long history, the science of conservation tillage is contemporary.

INTRODUCTION

History of Conservation Tillage

Conservation tillage has been around since humans first planted a seed by making a hole in the ground or spreading seeds on the surface of the soil. Conservation tillage can greatly reduce water- and wind-driven soil erosion. In spite of its long history, the science of conservation tillage is contemporary. The relationship between plant residues and the forces of soil erosion and soil quality parameters has been studied in depth only during this generation. As used in this entry, conservation tillage is an agronomic production system that leaves at least 30% of the soil surface covered with plant residue after the planting process. Laflen^[1] showed that 30% crop residue cover reduces soil erosion by 60%. This conservation practice can be utilized on both cropland and grazing lands. Protecting the soil from erosion is important for the maintenance of long-term productivity of the soil resource base. Conservation tillage also improves the quality of the soil by potentially increasing the soil organic matter and generally improving the soil quality.

Concept of Conservation Tillage

Conservation tillage or crop residue management systems range from no-till or direct-seeding methods to reduced tillage systems that disturb the soil but leave the required amount of crop residue on the soil surface after planting. Equipment used for no-till planting till only a narrow strip of soil or push aside the residue, so the planting can be completed with good soil-to-seed contact. Forage and

cereal crops can be broadcasted on the soil surface where they rely on the forces of nature such as frost or rain to incorporate the seeds into the soil. Reduced tillage equipment utilizes chisel plows, field cultivators, or disks that incorporate a portion of previous crop residue. The number of trips, speed, depth, and type of point used on the cultivation tool all affect the amount of crop residue incorporated. Sweeps and straight chisel points leave more residue on the surface than twisted chisel points.

SOIL EROSION

Soil erosion is a natural process that has been a major problem for all civilizations since recorded time began. Lowden^[2] had pointed out the tremendous impact soil erosion has had on great civilizations around the world. The loss of soil productivity and the effect the resulting sediment from the eroding fields of both cropland and grazing lands have, in many cases, hastened or even caused the demise of some of these past societies. Modern governments have begun to recognize that many practices lead to the accelerated soil erosion that affects the productivity of the land unit, and the displaced sediment causes many other problems. Many recognize the importance of sustaining the soil resources not only for food and fiber production, but also for the economic savings to communities. Sediment removal is a costly endeavor for many communities and governments in order to maintain drainage ditches, irrigation canals, shipping and boating channels, water storage reservoirs, and lakes for flood control. Sediment also lowers water quality and increases water treatment costs for drinking and other uses. The deposition

of eroded soil interferes with the utilization of the land resources and often requires removal or incorporation into the existing soil.

THE ECONOMICS OF CONSERVATION TILLAGE

Conservation tillage has been a major part of the conservation program in the United States since the 1970s. It is the primary conservation practice used to control soil erosion on cropland. Conservation tillage is also used to control soil erosion on grazing lands when establishing a forage crop or introducing a new forage species to an existing pasture or rangeland. Conservation tillage systems generally require more management and have less opportunity for adjustment in decisions, but they are considered to be the most cost-effective tillage systems due to the often significant reduction in fuel and labor costs as well as investment in machinery.

CONSERVATION TILLAGE EFFECTS ON SOIL QUALITY

Conservation tillage improves soil quality by improving soil structure and soil tilth by increasing the soil organic matter. Tilling the soil oxidizes organic matter and exposes it to erosion. The less tillage performed, the more organic matter will be in the soil profile. Humus is the stable portion of the soil organic matter. Humus aids in binding soil aggregates together and increases the cation exchange capacity. These strong soil aggregates create a porous soil that allows both water and air to move freely. This porous condition is ideal for plant root growth. The increase in soil organic matter increases the water-holding capacity of the soil, increases the water infiltration rate, and decreases runoff.^[3] Soil organisms flourish under conservation tillage systems.^[4] The more plant residue left in the field, the more soil organisms are there in the soil. Bacteria, fungi, algae, protozoa, nematodes, earthworms, and insects are all working in the soil profile breaking down organic matter and providing a biodiverse community. The plant residues provided by conservation tillage feed the soil biology.

SOIL CONSERVATION BY GRASSLANDS

In addition to the many techniques described above for conserving soil and water resources, the use of forages, either as a permanent soil cover or in some rotational system with crops for direct human use, may be the most effective of all techniques for soil and water conservation. Historically and prehistorically, natural grasslands and shrublands have supported large populations of plant eaters (herbivores), which have grazed and/or browsed these resources. These plant eaters have then been the source of food for a variety of carnivores (meat eaters) and omnivores

(mixed diet of plant and meat). Grazing lands include the tundra of the arctic regions, the great temperate region grasslands, and the savannas of the tropical regions. These growing plants convert solar energy by the process of photosynthesis into chemical energy (primarily carbohydrates), and then, some are transformed by complex biochemical processes into lipids, amino acids and proteins, and vitamins, which are the nutrients needed by all multicellular life.

GRASSLAND UTILIZATION

The most abundant carbohydrates in nature are the structural compounds of cellulose and hemicellulose and in mature plants increasing levels of the derived lignin. Higher animals do not digest these compounds, but the anaerobic intestinal microorganisms can degrade cellulose and hemicellulose to usable end products, while lignin, though somewhat degraded, cannot be utilized at all. Herbivores have an enormous population of these anaerobic microorganisms either in the forestomachs (before the true gastric stomach, therefore called pregastric digesters) or in the caecum and colon (therefore called postgastric digesters). These microorganisms produce short-chain fatty acids, gases, and microbial cells. The fatty acids provide 60–80% of the host animal's energy, the gases are waste products, and the microbial cells are digested to amino acids, carbohydrate, fats, minerals, vitamins, or excreted in feces, depending on the pre- or postgastric anatomy. Thus, these structural carbohydrates not digestible by humans and higher animals are converted into usable products like meat, milk, cheese, hides, and wool for human utilization and benefit.

GRASSLAND HISTORIC BENEFITS

In the natural environment, wild herbivores were migratory, and many species traveled as much as 1200–1500 miles on their migratory routes. This meant that grazing pressure was heavy for a relatively short period as the animals passed through, but that extensive periods without grazing allowed plants to recover and maintain high levels of root energy reserves. These grasslands therefore accumulated very significant organic matter in the soils, and most of the high organic matter soils of the world developed under grasslands (which is an important mechanism in sequestering carbon). The notable exception to this statement is a forest growing in swamps or bogs where the leaves and small branches fall into water in an anaerobic or reduced oxygen environment, as opposed to the normal dry aerobic environment where oxidative processes re-release the sequestered carbon with significantly reduced yearly gain. Arctic areas have low oxidation rates for much of the year because of low temperatures and therefore reduced the rates of organic matter degradation.

OVERGRAZING PROBLEMS

Domestication and fencing of land have destroyed migratory patterns in much of these grasslands and rangelands. This is especially true in those areas of sufficient rainfall for relatively high productivity. The tendency therefore has been to graze continually, inevitably resulting in the depletion of root energy reserves, reduced soil organic matter during much of the year, and, therefore, reduced rates of organic matter production. The density of plant cover is reduced, and the time needed for plant growth to recover after grazing is increased. These processes increase the probability and quantity of soil erosion and reduce the efficiency of water infiltration into the soil. Continuous overgrazing is one of the major causes of desertification, and either the reduction of animal concentration or reduction in the length of the grazing period is necessary to prevent overgrazing.

RESEARCH

Long-term research has been conducted at the U.S. Department of Agriculture North Appalachian Experimental Watershed near Coshocton, Ohio, where precipitation, surface water runoff, and sediment loss in that runoff have been measured. In Table 1, which is composed of data from two articles by Owens, Edwards, and Van Keuren,^[5,6] precipitation, surface runoff, and sediment load were measured. Data from an unimproved pasture ungrazed (2 years), grazed only during the grazing season (3 years), and grazed during the growing season and winter hay feeding (6 years) were taken and summarized here. A similar sloped wooded watershed nearby was also sampled for the same measures. Note that by comparing the 3-year data, it is apparent that less surface runoff occurred from unfertilized pasture grazed during the growing season only (203 mm/yr) than from a similar sloped, wooded watershed nearby (261 mm/yr). Also note that for the 6-year data presented by Owens, Edwards, and Van Keuren,^[5,6] there was less annual surface runoff (137 mm/yr) from pasture (grazed and imported winter fed hay) than from the wooded watershed (173 mm/yr). The lower values for runoff recorded in the pasture watershed as compared to the wooded watershed occurred even though precipitation levels in the pasture watershed were higher than that in the wooded

watershed. Also note that the data from the storm of September 13, 1979, recorded a significantly higher sediment load that was carried in surface water runoff from the wooded watershed (1032 kg/ha) as compared to the load from the grazed pasture watershed (739 kg/ha), even though surface runoff from the pasture was 6 mm greater.

MANAGEMENT INTENSIVE GRAZING (MIG)

Subsequent research studied moderately fertilized and heavy fertilized pasture with rotational grazing as well as continual grazing. Many interesting conclusions reached from these studies and others in the eastern and Midwestern areas of the United States have led to the development of what are commonly called MIG systems. MIG systems are described below. The principles followed in MIG are designed to easily meet the animals' nutrient needs and thus their productivity levels while at the same time to keep pasture plants in the immature or boot-prebud stage of growth; when root reserves have been restored, rapid regrowth can be expected. To accomplish this goal, sufficient cells or grazing paddocks are needed, so that animals remain in individual paddocks no more than three days to prevent animals from grazing new regrowth, and so that at least 3–4 in. of leaf remain, although regrowth is rapid. The plant species used are a function of moisture supply, latitude, fertility, etc., but the MIG system increases plant diversity and maximizes ground cover over time.

MIG BENEFITS—CONSERVATION AND ECONOMICS

The advantages of MIG include greatly reduced soil erosion with the improved air and water quality this entails. MIG greatly improves plant vigor, production, and diversity and improved fish, game bird, and wildlife habitat. The increased organic matter accumulating in soils allows a higher percentage of rainfall to infiltrate where it can be used to stimulate plant growth rather than runoff and to increase sedimentation problems in streams. The animal wastes (manure and urine) are more evenly distributed by MIG than by other grazing systems, allowing those nutrients to be recycled through the plants to the animals without getting into runoff water. In research performed at the

^aData from the storm of September 13, 1979—the worst storm in more than a century.

North Appalachian Experimental Watershed, water quality in pastured watershed was found to be as good or better than both surface and groundwater from an adjacent woodland watershed. In total, grazing lands properly used are one of the best tools to conserve water and soil resources, to sequester significant quantities of atmospheric carbon dioxide,^[7] and to provide an excellent economic return to the producer by converting for ages into higher valued animal products for human use.

Abstract

Land that has been conserved for natural resource protection requires careful and ongoing management. There are many factors that can degrade protected lands. These include changes in native plant or animal communities caused by pests, pathogens, or invasive species; poaching; illegal resource harvesting; disturbance to plants and animals from intensive human use; malicious destruction of resources; and ecological changes in nearby landscapes. Every protected property, regardless of size, must have an explicit conservation goal, a management plan, stewardship consistent with the management plan, monitoring to determine whether management goals are being achieved, and adaptive adjustment of management plans if goals are not being met or new threats to the integrity of the protected land emerge.

INTRODUCTION

Acquiring ownership of, or development rights to, land is one of the most effective ways of conserving natural and cultural resources at local, regional, and national scales. Once acquired, the protected land requires constant stewardship. Land protection is done for many reasons: to protect the fauna and flora of a site, to protect cultural resources, to ensure that ecosystem services are maintained, to allow sustainable use of natural resources of the site, and to afford public access for recreational purposes.^[1,2] Land conservation occurs at multiple scales, in all ecosystems (terrestrial, aquatic, and marine), and is accomplished by many kinds of institutions and public agencies. National governments protect watersheds, forests, and rangelands for resource protection and, in many cases, for sustainable resource harvesting. National governments also conserve large national park systems for the benefit of biota and present and future generations of citizens. Conservation occurs at smaller jurisdictions as well, e.g., states, counties, and towns. Large nonprofit organizations, such as The Nature Conservancy and the Audubon Society in the United States, are very effective in protecting land as are small nonprofit organizations such as local land trusts and conservancies. Regardless of the size of the conservation organization or the property preserved, all protected lands require ongoing management and stewardship.

The consequences of not stewarding protected lands can jeopardize the very resources that are meant to be preserved. Developing and implementing a management plan for protected land are good ways of cataloging and prioritizing stewardship responsibilities, and we review steps in management planning here. Threats to protected lands can rapidly change; therefore, monitoring protected lands is an important part of the process. Finally, the technical knowledge within a conservation organization, the availability of staff and equipment, and funding for protected land management are frequently inadequate for the magnitude of the task; thus, innovative collaborations and efficient implementation of management plans are necessary.

Protected land stewardship is a challenging endeavor and has many components, which will be reviewed here. Large government agencies or other organizations that own and manage large areas of protected lands typically have dedicated programs for stewardship activities. For example, the National Park Service (NPS) oversees a large and complex network of protected areas in the United States. Every park in the NPS system has a general management plan, which articulates the management needs of a park and how the park will meet those needs.^[3] Furthermore, the NPS has a sophisticated program—the NPS Inventory and Monitoring Program—to systematically monitor environmental conditions in parks to know whether management and stewardship activities are having the desired results and to be vigilant to new or unforeseen threats to the ecological

integrity of a park.^[4] Other conservation agencies that oversee large areas of land have similar programs such as the U.S. Fish and Wildlife Services,^[5] U.S. Bureau of Land Management,^[6] and U.S. Forest Service.^[7] Small conservation organizations, such as local conservancies and land trusts, typically do not have dedicated staff or program resources for protected land stewardship, yet they own significant areas of land. In the United States, e.g., there are 1700 different land trusts that control over 150,000 km² of land.^[5] The focus of this entry is to describe the conservation land stewardship process that would be followed by a small conservation organization.

LAND PROTECTION AND STEWARDSHIP

There are a variety of reasons to protect land and many stewardship strategies that can be used to meet conservation goals (Table 1). Conservation lands are typically protected by securing fee simple ownership, control over future development rights, or establishment of permitted and restricted uses of the land through zoning controls.^[2]

Table 1 Examples of common conservation goals and management activities that achieve them.

Goal	Management and stewardship actions
Preserve biodiversity	Protect large tracts of land. Connect separate refuges with corridors. Increase the size of refuges. Enforce policies against poaching wildlife or harvesting plants. Ensure adjacent land uses are not a source of invasive species, pests, or pathogens. Monitor for invasive species, pests, and pathogens. Monitor population levels of key or indicator species of plants and animals.
Preserve cultural resources	Protect sites or regions of interest; limit public access to sensitive sites.
Preserve ecosystem services	Ensure that conservation land boundaries encompass whole watersheds, maintain diversity of habitats, and allow public access and nondestructive forms of recreation so that patrons can benefit from aesthetic values.
Preserve aesthetic or recreational values	Provide trails and interpretive services for public access; encourage hiking, hunting, and fishing if appropriate for the site; and manage views and soundscapes to preserve natural conditions.
Ensure sustainable resource use	If a site permits, allow controlled harvest of sustainable resources, such as wood products, game and fish, plants, fruits, berries, and fungi.
Agricultural preservation	Obtain development rights and easements to working lands and waters to ensure they will remain in agricultural land use.

However a property is controlled, the development and implementation of an ongoing management plan for the protected property are essential. There are many threats to the ecological integrity of protected lands (Table 2 and Fig. 1). Pests, pathogens, and invasive species can impact native fauna and flora of a site. Illegal poaching or harvesting natural resources can diminish the biota. Soil compaction, erosion, and vegetation disturbance in fragile ecosystems caused by motor vehicle riding (e.g., all-terrain vehicles and motorcycles) can result in serious environmental damage. Malicious acts, such as garbage dumping, littering, theft of cultural resources, and vandalism, can diminish the aesthetic value of a site. A carefully designed management plan will be attentive to these threats. Protected land management should happen in a systematic manner (Fig. 2). The basic steps are discussed in detail in the coming sections.

Site Assessment and Baseline Inventory

An essential first step in conservation land management is a site (the parcel) and landscape (what is around it) survey to inventory existing conditions and catalog important habitats. The purpose of site assessment is to evaluate the presence and condition of important natural resources and to identify threats to the focal resources and the ecosystem as a whole. Target resources can be species, habitats, rivers, landforms, views, farms, cultural resources, groundwater, or ecosystem services and ecological processes.^[8,9] Site assessment can be a complex activity and require personnel familiar with local ecological conditions. Assessment involves field survey and consolidation of relevant geospatial information such as data from geographic information systems (wetlands, rare species occurrences, land use, soils, landform, etc.), digital imagery, and the results of previous reconnaissance of the area if available. The initial site assessment establishes a baseline condition for easement monitoring and tracking changes in the condition of

Table 2 Examples of common threats to resources on conserved lands.

Resource	Threat
Biodiversity	Habitat destruction, poaching; illegal harvest of plants or animals; spread of invasive species, pests, and pathogens; loss of fitness due to small population sizes; and illegal motor vehicle access in sensitive habitats.
Cultural resources	Vandalism, theft, and alteration of landscape context (e.g., views, soundscapes).
Ecosystem services	Groundwater withdrawal outside refuge, habitat destruction on borders of refuge, and high-impact land uses outside refuge in watershed.
Aesthetic or recreational values	Trespassing, illegal motor vehicle access, dumping, and degradation of natural views or soundscapes.

Fig. 1 Examples of threats to protected lands: (A) vandalism (destruction of signage); (B) illegal dumping of refuse; and (C) all-terrain vehicle track damage to wetland habitat.

the property. Landscape analysis provides a regional context for conservation and provides insight into gains and losses of dispersal corridors, up watershed threats that would jeopardize site-level habitats or species, and land use changes on nearby properties that might enhance or diminish the conservation value of a particular parcel.^[10] There is a growing number of protocols that have been advanced to perform a baseline inventory.^[11,12]

Development of Management Goals and Plan

Development of management goals is an essential step, and the goals of the management plan will reflect the values of the conservation institution and the purpose of acquiring the conservation land.^[13] Common management goals include stewarding the land for water (ground and/or surface) protection, conservation of biodiversity, forestry, farming, aesthetic values, fish and wildlife management, and recreation

(hiking, paddling, fishing, hunting, etc.). Management goals of one property can affect the viability of nearby conservation properties owned by others; hence, there is a need for coordinated management when protected lands are in a mosaic of small parcels managed by different institutions. It is important that a management plan establishes a basis or rationale for prioritizing resources and stewardship actions so that scarce resources applied over time can still achieve large, long-term goals. Once goals for a property are established, a management plan should be developed and clear measures of success must be identified. These measures are the basis for ongoing monitoring and are the indicators of success or failure of the management plan.

Implementation of Management Plan

Management plans can vary in complexity; simple management plans for conservation lands may require little activity

Fig. 2 Management cycle of protected lands: Steps involved in managing protected lands.

beyond periodic monitoring. Other stewardship activities, however, could require considerable work, expertise, and investment in personnel, supplies, equipment, and time in the field. Examples of expensive and complex management tasks include habitat restoration, creating and maintaining trail systems, forest management (selective cutting to maintain the age and target species composition of the forest), and removal or control of invasive species.^[14,15] The implementation of a management plan can be a challenge for conservation organizations. Large land owners do not always have the staff or resources to manage extensive properties. Similarly, small, local conservation organizations, such as land trusts, rarely have the technical wherewithal or financial ability to take on complex management activities. Partnerships and collaborative projects are one way to perform complex stewardship tasks.

Monitoring

Vigilant monitoring is required of conservation properties and the land surrounding them. Easements must be monitored on a regular basis to ensure that fee owners are managing properties in a manner that is consistent with the easement that is held by the conservation organization. Violations in easements will have legal and policy ramifications, which need to be addressed.

All properties must be visited on a regular basis to protect against adverse possession claims and to identify inappropriate human activities occurring on or near them. Vandalism, dumping, erosion caused by motor vehicles, illegal hunting, and wood cutting are, unfortunately, common on conservation lands (Fig. 1). Monitoring for disturbances such as these is relatively straightforward for small properties but requires constant attention. Monitoring over large, expansive conservation lands can be logistically difficult, especially if access is difficult.^[16] Ecological monitoring must be done on and around conservation lands to ensure that invasive plants and animals have not become established, pests or pathogens are not present, stewardship activities are yielding desired outcomes, target species are still present, and ecosystem health remains high. Regional changes in the creation of impervious surfaces, which increase storm water runoff, water withdrawal in the watershed, land use conversion, and habitat fragmentation can degrade the condition and viability inside conservation lands.

Synthesis, Reflection, and Adaptive Stewardship

Monitoring provides the data from which decisions about the efficacy of the management plan can be made. A careful analysis of monitoring data determines whether the management plan is working and the ecological condition of the property is changing. If the desired results are not occurring, the management plan should be modified to meet the conservation goals of the property. This is a critical step and follows the logic of the adaptive management paradigm.^[17] New, unanticipated stewardship challenges can emerge rapidly. Management plans must be dynamic documents and capable of changing as knowledge or needs require.

CONCLUSION

Acquiring land is an effective way to protect natural resources, and careful stewardship of conserved lands ensures that the condition of the natural resources is preserved. Stewardship is an ongoing process and a long-term commitment. Many factors can diminish the value of protected land, and these must be monitored and, when present, mitigated. The process of protected land management has a number of steps and begins with a careful resource inventory of the protected property and establishment of a suite of management goals that will direct stewardship activities. Ongoing monitoring to ensure that management goals are being met is an essential component of the process.

Large land owners, such as U.S. NPS or U.S. Forest Service, have very complex management programs to ensure that the property in their care retains the environmental and cultural resources the lands were obtained to protect. Small land owners, such as land trusts and local

conservancies, frequently do not have dedicated staff resources, knowledge, or budgets to steward their land, but innovative partnerships are one way the resources of many institutions can be leveraged to achieve effective land stewardship even by small land owners. One model is the Rhode Island Conservation Stewardship Collaborative (RICSC),^[18] an alliance of federal, state, municipal, and nonprofit conservation organizations who partner to (from its mission statement) “. . . advance long-term protection and stewardship of terrestrial, aquatic, coastal, estuarine, and marine areas in Rhode Island that have been conserved by fee, easement, or other means.” The RICSC tackles systemic, state-wide, impediments to good conservation land stewardship and provides training materials, protocols, and technical capacity to assist conservation land owners in their stewardship challenges.

ACKNOWLEDGMENTS

The following individuals have provided us thoughtful guidance and support for our work in conservation land management and stewardship: Julie Sharpe, Peggy Sharpe, Rupert Friday, Cathy Sparks, Scott Ruhren, Sharon Marino, Larry Taft, Jennifer Pereira, Charles Vandemoer, and Kathleen Wainwright. The Rhode Island Conservation Stewardship Collaborative has challenged us to develop procedures, protocols, and guidance for conservation agencies, especially local land trusts, in supporting their protected land management. The University of Rhode Island Cooperative Extension program, URI Department of Natural Resources Science, and USDA Renewable Resources Extension Act have steadily supported our work in conservation land management and stewardship.

Consistence

Ray McBride

Department of Land Resource Science, University of Guelph, Guelph, Ontario, Canada

Abstract

Soil consistence and consistency are closely related terms used by pedologists and soil engineers, respectively, to describe the degree of resistance to deformation or rupture exhibited by a structured soil when subjected to externally applied mechanical stresses. This aspect of a soil's rheological behavior, however, has only ever been characterized with semiquantitative criteria. Soil profiles are routinely characterized for their consistence by horizon as part of a soil morphological description, which can aid in making pertinent soil survey interpretations for common land uses, where knowledge of soil strength is an important consideration. Soil consistency limits are gravimetric soil water contents that correspond to arbitrary boundaries defining the liquid, plastic, and semisolid states as measured by simple laboratory tests. The term *consistency*, however, was originally used by soil engineers with reference to a simple field test of soil resistance to penetration by a thumb or thumbnail, when the specimen was at field water content.

INTRODUCTION

Soil consistence and consistency are closely related terms used by pedologists and soil engineers, respectively, to describe the degree of resistance to deformation or rupture exhibited by a structured soil when subjected to externally applied mechanical stresses. This aspect of a soil's rheological behavior, however, has only ever been characterized with semiquantitative criteria. One of these criteria is that the test soil should be under one or more prescribed (and stated) conditions of initial soil wetness (e.g., dry, moist, and wet), as these properties are highly dependent on soil water content (Fig. 1). These soil properties are a manifestation of the combined forces of adhesion/cohesion that contribute to: 1) the attraction between soil particles and pore water and 2) the attraction of soil particles to one another. As a result, particle-size distribution, organic matter content, clay mineralogy, soil solution chemistry (adsorbed cations), soil fabric, sample pretreatment, etc. also have a large influence on these properties. Classes or ratings of soil consistence are commonly determined by pedologists with simple manual field tests that involve the application of compressive forces to a structurally intact soil specimen (e.g., clod) until *rupture* occurs. Conversely, soil consistency classes or ratings are routinely used by soil engineers in the classification of soils used for engineering purposes, but in this case the field tests usually involve defining the soil resistance to *penetration* by a blunt object (e.g., thumb/thumbnail, blunt end of a pencil, etc.).

SOIL CONSISTENCE

Soil profiles are routinely characterized for their consistence by horizon as part of a soil morphological description, which can aid in making pertinent soil survey interpretations for

common land uses (e.g., agriculture), where knowledge of soil strength is an important consideration (e.g., tillage and traffic). Simple field tests for soil consistence at prescribed water contents have been developed by the U.S. Department of Agriculture–Soil Conservation Service^[1] and have been adopted by pedologists in many other countries including Australia^[2] and Canada.^[3]

The principal field test involves compressing an unconfined, block-like specimen between the extended thumb and forefinger, between both hands, or between the foot and a non-resilient flat surface (Table 1).^[1] Rupture resistance to compressive stress is indirectly related to the tensile strength (i.e., the load per unit area at which an unconfined cylindrical specimen will fail in a simple

Fig. 1 Generalized schematic of consistency states and shrinkage behavior of clay-rich soils.

Table 1 Terms for describing consistence (rupture resistance) of block-like specimens.

Soil consistence classes at prescribed soil wetness conditions			Field test description	
Moderately dry and very dry	Slightly dry and wetter	Air-dried, then submerged	Operation	Approximate force/energy applied ^a
Loose	Loose	Not applicable	Specimen not obtainable	—
Soft	Very friable	Non-cemented	Fails under very slight force applied slowly between thumb and forefinger	<8 N
Slightly hard	Friable	Extremely weakly cemented	Fails under slight force applied slowly between thumb and forefinger	8–20 N
Moderately hard	Firm	Very weakly cemented	Fails under moderate force applied slowly between thumb and forefinger	20–40 N
Hard	Very firm	Weakly cemented	Fails under strong force applied slowly between thumb and forefinger (80 N is about the maximum force that can be applied)	40–80 N
Very hard	Extremely firm	Moderately cemented	Cannot be failed between thumb and forefinger but can be between both hands or by placing on a non-resilient surface and applying gentle force underfoot	80–160 N
Extremely hard	Slightly rigid	Strongly cemented	Cannot be failed in hands but can be underfoot by full body weight (approximately 800 N) applied slowly	160–800 N
Rigid	Rigid	Very strongly cemented	Cannot be failed underfoot by full body weight but can be by a <3 J blow	800 N–3 J
Very rigid	Very rigid	Indurated	Cannot be failed by a blow of <3 J	≥3 J

^aBoth units of force (Newtons, N) and energy (joules, J) are used.

Source: From Soil Survey Division Staff.^[1]

tension test).^[4] In Table 1, approximate values of applied force/energy for the various classes are provided. If induration with cementing agents is suspected (e.g., organic substances, calcite, silica, and sesquioxides), the specimen is air-dried and then submerged in water for at least 1 hour before manual compression testing takes place (Table 1). Apart from brittle fracture (rupture), however, soil specimens can fail in different manners (e.g., plastic deformation, flow, and smearing) and meaningful categories can also be determined manually in the field (Fig. 1).^[1]

Other related tests that can be performed on structured, confined soil include resistance to penetration with a commercially available, inexpensive “pocket penetrometer” (i.e., the pressure required to push a 6.4-mm diameter cylindrical rod a distance of 6.4 mm into the soil within 1 second).^[1] Related field tests on puddled, unconfined soils include plasticity (permanent deformation at constant volume without rupturing as force is applied), toughness (manual force needed to perform the plastic limit roll test), and stickiness (capacity of a soil to adhere to other objects). The plasticity and toughness tests used by pedologists were originally derived from soil engineering practice.^[5]

SOIL CONSISTENCY

Soil consistency (or Atterberg) “limits” are gravimetric soil water contents that correspond to arbitrary boundaries defining the liquid, plastic, and semisolid states as measured by

simple laboratory tests^[6] (Fig. 1). The term “consistency,” however, was originally used by soil engineers with reference to a simple field test of soil resistance to penetration by a thumb or thumbnail, when the specimen was at field water content.^[5] There has been no attempt by the American Society for Testing and Materials to standardize their test

Table 2 Terms for describing consistency (penetration resistance) of cohesive material at field water content.

Soil consistency term	Field test description	Approximately undrained shear strength (kN/m ²)
Very soft	Easily penetrated, several centimeters by fist	<20
Soft	Easily penetrated several centimeters by thumb	20–40
Soft to firm	—	40–50
Firm	Moderate effort needed to penetrate by thumb	50–75

method using a pocket penetrometer or similar device,^[5] but approximate values of undrained shear strength have been assigned to consistency classes of cohesive soils (Table 2). Soil engineering tests for cementation^[5] are performed manually by applying pressure on structured, unconfined specimens, as in Soil survey division staff,^[1] but do not involve submersion in water prior to testing.

Only soils with significant clay contents (i.e., “plastic” or “cohesive” soils) have measurable Atterberg limits, and they are among the most meaningful and widely interpreted of soil engineering test indices. Applications include being used to estimate the shear strength and bearing capacity, compressibility, permeability, swelling potential, and specific surface of soils.

Consolidation

Tarunjit Singh Butalia

Civil and Environmental Engineering, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Consolidation is the reduction in volume of soil caused by the movement of water out of a soil mass. The term is commonly referred to as primary compression. The rate of consolidation is an important property of a soil mass because water has to move in the direction of decreasing potential for consolidation to occur. It is the movement of water rather than the compression of air-filled voids, which distinguishes consolidation from compaction. The magnitude of consolidation for coarse-grained soils (sand and gravel) is much less compared to fine-grained soils (clay and silt). However, because fine-grained soils exhibit low coefficient of permeability, the rate of consolidation in fine-grained soils is much slower than coarse-grained soils.

THEORIES AND ANALYSES

Consolidation analysis generally focuses on saturated soils. When an external load is applied on soil or if the vertical stresses increase for saturated soils, the pore water pressure increases immediately by an amount equal to the increase in applied stress. Gradually, some of the pore water moves out of the soil mass in the direction of decreasing potential, thus transferring the stresses from the water particles to the soil skeleton. This results in reduced volume of the soil. During the consolidation process, the volume of the soil particles remains unchanged, while the volume of the water-filled voids is reduced.

One of the first soil consolidation laboratory experiments was presented by Frontard.^[1] He placed clay samples in metal containers and loaded the samples with a piston. Meantime, Forchheimer^[2] was the first to propose a mathematical model for consolidation analysis. While the mathematical formulation was simple, it was not very accurate because of incomplete understanding of the concept of effective stress. Terzaghi,^[3] one of Forchheimer's former students, was the first person to recognize clearly the concept of effective stress and its application to the soil consolidation problem.

Terzaghi's theory of consolidation, relating soil compression and effective stress as well as the rate of consolidation, is considered to be the advent of modern soil mechanics. Terzaghi's simple theory assumed a saturated clayey soil, the void ratio–logarithm of effective stress relationship to be linear, and that the soil properties do not change during the consolidation process. The analysis was carried out for 1-D (axial) settlement with no radial deformations. For a homogeneous soil layer of thickness H with initial void ratio e_0 , the

amount of 1-D consolidation settlement due to Δe decrease in void ratio is

$$\Delta H = \frac{\Delta e H}{1 + e_0} \quad (1)$$

In most cases, the decrease in void ratio is generally expressed in terms of compression index or coefficient of compressibility and change in effective stress. The rate of consolidation is affected by several factors including soil, stratum, and loading properties. Soil properties of interest include soil permeability, void ratio, and compressibility. Stratum factors include the thickness of the layer under consideration as well as the drainage conditions surrounding the layer. Loading factors include the ratio of the new loading to original loading. The soil properties are commonly modeled through the coefficient of consolidation (c_v) as follows:

$$c_v = \frac{k(1 + e)}{a_v \gamma_w} \quad (2)$$

where k is the coefficient of permeability, e is the in-place void ratio, a_v is the coefficient of compressibility, and γ_w is the density of the pore fluid (typically water). The governing equation of 1-D diffusion as applied to transient water flow is as follows:

$$\frac{\partial u}{\partial t} = c_v \frac{\partial^2 u}{\partial z^2} \quad (3)$$

Eq. 3 is solved to obtain the rate at which consolidation occurs.

Oedometer or 1-D consolidation laboratory test (ASTM D2435)^[4] is used to evaluate the consolidation characteristics of a soil sample. The test involves applying varying

Fig. 1 Consolidation test apparatus.

Fig. 2 Idealized axial compression vs. time plot.

Fig. 3 Idealized void ratio vs. axial effective stress plot.

levels of stress on a soil sample that is confined in the radial direction and allowed to drain and compress axially (Fig. 1). Data collection for the test mainly consists of axial compression vs. time readings for each stress loading and unloading process (Fig. 2). The ultimate void ratio for each loading and unloading step can then be plotted against the logarithm of the vertical (axial) effective stress (Fig. 3). The slope of the virgin curve is referred to as the compression index (C_c), while the slope of the

Fig. 4 Typical axial compression vs. time plot for clay and sand at specified effective axial stress.

Fig. 5 Typical void ratio vs. axial effective stress plot for clay and sand.

recompression or unloading curve is referred to as the recompression index (C_r). Typical consolidation test curves for clay and sand samples are shown in Figs. 4 and 5. Compression and recompression index values less than 0.2 represent soils with low compressibility. Values between 0.2 and 0.4 indicate moderately compressible soils, while values larger than 0.4 represent highly compressible soils. Accurate laboratory evaluation of coefficient of consolidation values can be challenging because of its dependence on permeability coefficient (k), coefficient of compressibility (a_v), and potential sample disturbance. The average coefficient of consolidation varies from 10^{-8} to 10^{-6} m²/s. For controlled-strain loading testing of soil samples, test method ASTM D4186^[5] should be used.

Terzaghi's theory and the 1-D laboratory experiment based on it are used extensively by engineers for consolidation analysis. However, the stringent soil behavior and modeling considerations in Terzaghi's theory limit the use of the theory for predicting pore water pressure responses and settlements (amount and rate) in complex situations. Alternatively, non-linear consolidation models proposed by Schiffman,^[6] Gibson,^[7] Tse,^[8] Scott,^[9] and Leroueil^[10] can be used. Many of these models allow for a non-linear variation of void ratio with logarithmic effective stress and the change in soil permeability as consolidation occurs. Additional technical

information on soil consolidation can be obtained from the studies by Wu,^[11] Mitchell,^[12] Terzaghi,^[13] Coduto,^[14] McCarthy,^[15] and DeBoer.^[16]

Controlled Traffic

Randall C. Reeder

*Food, Agricultural and Biological Engineering Department, Ohio State University,
Columbus, Ohio, U.S.A.*

Abstract

Controlled traffic eliminates worries about soil compaction and improves overall farm efficiency and economics. Auto-steering is recommended, especially for large equipment, because it makes a controlled traffic system easier to set up and follow. Controlled traffic systems work with no-till and other tillage systems and with most major crops.

INTRODUCTION

Controlled traffic is a method to manage soil compaction. Compaction is “managed” by assuring that all heavy traffic is confined to specific lanes through the crop, year after year. The lanes become compacted, and the soil between lanes is never driven on.

Controlled traffic is an ideal match for most conservation tillage systems. A global positioning system-based guidance system makes it possible to till the entire surface and follow the permanent lanes. With controlled traffic, field efficiency and crop yields increase and the cost of inputs (pesticides, seed, labor, and fuel) decrease. Many farmers convert all of their machinery to controlled traffic at one time, while others choose to reduce or eliminate the extra cost by moving to controlled traffic gradually as equipment is replaced. Maximum advantages of controlled traffic occur when the operating width of all equipment is matched and tire spacings are set to minimize the trafficked area.

The first step to controlled traffic is to make all equipment cover the same width or multiples of that width. For big grain farms, the combine harvester will likely be the determining factor; e.g., if the grain head is 36 ft (11 m), the drill or air seeder might be 35 ft (10.7 m), and the sprayer either 70 ft (21.3 m) or 105 ft (32 m) wide. For a farm with row crops [e.g., corn in 30-in. (750 mm) rows], the combine could be 12-row, the planter either 12- or 24-row, and the sprayer either 60 ft (18.3 m) or 90 ft (27.4 m) wide. A farm operation with a 16-row corn head would have similar multiples for the planter and sprayer. If the same farm raises small grains or soybeans, the drill, air seeder, and grain head must match these widths. For smaller operations, the basic width might be 15 ft (4.5 m) or 20 ft (6 m).

The second step is to look at the tires (or tracks) of all vehicles in the field. The goal is to minimize the number of traffic lanes and the width of those lanes. Any equipment (sprayer and cultivator) driven through a growing crop must use the traffic lanes, and the tires should fit between the rows.

A combine or four-wheel drive tractor with wide tires is satisfactory, but the goal would be to go to narrower tires (maybe split duals) using the same traffic lanes ([Table 1](#)).

Controlled traffic improves traction, flotation, and timeliness of planting, spraying, and harvesting while minimizing potential yield losses from compaction. Compaction is managed, not eliminated. Controlled traffic takes the advantage of compaction where it is beneficial. Compacted soil under wheel tracks provides better flotation and improved traction, especially on wet soil. Controlled traffic eliminates compaction where it is a detriment (under and close to rows) and leads to better water infiltration, root development, and fertilizer uptake.

Controlled traffic eliminates overlaps and skips during pesticide and fertilizer application and while seeding crops. Overlaps often waste 10–15% of chemicals, drilled seed, fuel, and all other machine operation expenses. Precisely placed traffic paths can eliminate the waste and more than offset the expense of establishing and maintaining the controlled traffic system.

NO-TILL

One concern farmers have about no-till is the potential for compaction and ruts caused by driving on wet soil. Controlled traffic removes most of that concern. Controlled traffic provides for potential yield increases by restricting compaction to trafficked lanes. The stalks or skip rows remaining from the previous year's crop provide visual guidance at planting ([Fig. 1](#)). Auto-steering systems are extremely accurate and can eliminate any need for visual clues.

RIDGE TILL

Controlled traffic is an integral part of a ridge till system and is responsible for part of the yield advantages.

Table 1 Example traffic patterns for row crops.

No. of rows	Tractor (in.)	Combine (in.)	No. of paths	% Trafficked
30-in. (750-mm) row spacing				
6	60	120	4	44
6	120	120	2	22
8	120	120	2	17
8	60 and 120	120 and 180	6	50
12	60	120 (6-row)	4	22
16	60 and 120	120 and 180 (8-row)	8	33
24	60 and 120	120 and 180 (12-row)	12	33
36-in. (900-mm) row spacing				
6	72	144	4	37
8	72	144	4	28
12	72	144 (6-row)	4	18

Example wheel spacings for tractor and combine, single and dual tire options. Percent of the field trafficked assumes that each path is 20 in. (500 mm) wide.

All tires must be narrow enough and spaced properly to fit between the rows. Driving on the row with a combine or other heavy load significantly reduces yield in those rows the following year. If the ground is frozen solid, driving on the row does not harm the soil.

MULCH TILL

Auto-steering systems make it possible to use controlled traffic with mulch till systems. To maintain the full benefits of controlled traffic, tillage implements could be adapted by removing shanks that follow the tire tracks. The tillage implement would have to be the same width as the planter or drill.

Fig. 1 Permanent traffic lanes are easy to follow at planting.

BENEFITS

Timeliness of planting and harvesting is a major advantage of controlled traffic. Compacted paths provide a firm base for tractor and combine tires. Both flotation and traction are improved. Although not recommended, farmers with controlled traffic sometimes drive through standing water to plant without sinking or destroying soil structure. With controlled traffic, the absorption of water by the soil is greater except in the traffic lanes. Because the soil can store more water in the root zone, yields may improve in dry seasons, and runoff and erosion may be reduced.

Benefits related to chemical application may outweigh any other. Precisely spaced traffic lanes eliminate overlaps and uneven guess rows. Traffic lanes make it easy to spray at night, which usually improves the efficiency of the plant protection product. Eliminating waste from overlaps, and reduced yields from any gaps in application, may quickly pay for the extra investment in controlled traffic.

Controlled traffic helps retain any long-term benefits of subsoiling to alleviate compaction. With controlled traffic, repeated subsoiling is not needed because root zones under row crops are not compacted. Otherwise, as few as two passes of a tractor in the spring for shallow tillage and planting after fall subsoiling may recompact soil in the tire tracks to the same porosity as in non-subsoiled, non-trafficked areas. Wheel tracks become compacted even when relatively light machinery is used. With a typical plow-based cropping system, random trafficking would cover 75–90% of a field by the time planting is completed the second year, nearly eliminating the benefits of subsoiling.

Cotton research with no-till has shown yield reductions caused by shallow compaction, especially in a layer 2–4 in. (50–100 mm) below the surface.^[1] This surface compaction resulting from random wheel traffic could be minimized by controlled traffic.

With an automatic guidance system, the operator can devote attention to a machine’s performance instead of steering. The operator could literally look backward 90% of the time. Ease of driving minimizes fatigue allowing for longer work days.

IMPLEMENTING CONTROLLED TRAFFIC

Controlled traffic can work with, but is not limited to the following systems:

- continuous row crops;
- row crops in rotation with drilled beans or grain (requires skip rows);
- continuous small grains (using skip rows); and
- row crops/small grains, with cover crops.

Because the goal of controlled traffic is to drive on the least amount of soil, it is important that tire width be minimized and that wheels run in the fewest possible row middles (Table 1).^[2]

Corn and other Row Crops

Getting all wheels spaced properly is the major challenge with available equipment. For corn and other crops planted in rows, machinery could include a grain cart, manure spreader, fertilizer spreader, and sprayer. For continuous cotton, or continuous small grains, there are usually fewer machines to get aligned.

Cotton

Typical cotton rows are spaced at 38–40 in. (1 m). The wide rows allow adequate space for large tires. Where cotton is grown on beds or ridges, the maximum tire width would be about 10 in. less than the row spacing. A tire spacing of 80 in. (2 m) is a fairly easy adjustment for all equipment. Bigger tractors may have split duals spaced at 80 and 160 in. (2 and 4 m). Some cotton is grown in 30-in. (750-mm) rows making the wheel alignments similar to most corn production systems.

Site-specific subsoiling often improves cotton yields.^[3] Tilling just deep enough to eliminate the hard pan is compatible with a controlled traffic system and can provide the same yield advantage as subsoiling at a uniform depth.

Cotton is often planted in the same row position year after year, so controlled traffic is ideal. With controlled traffic, planters and cultivators would likely be twice as wide as the cotton harvester. Harvesters are usually 4-row, with some 6-row units.

Small Grains

For small-grain production, a major benefit from controlled traffic is in sprayer operation efficiency. Controlled traffic lanes allow the sprayer operator to drive accurately, even at night.

Examples

An example of an optimum system is the tractor and combine on single tires with the same spacing, making only two tracks with 8-row equipment (Figs. 2 and 3). The section width of the tires should be several inches less than the row spacing (e.g., 22 in. (550 mm) for 30-in. (750 mm) rows). Less than 20% of the soil would be trafficked, leaving more than 80% of the soil in good condition for root growth. Even a combine with split duals and a tractor with narrow wheel spacing (six tracks with 8-row equipment) would result in only about half of the soil being driven on. The

Fig. 2 An 8-row combine with single tires is a key part of one controlled traffic system.

rows between adjacent tracks would have a strip of uncompacted soil about 8 in. (20 mm) wide.

With narrow row spacings of 20 or 15 in. (50 or 38 mm), installing tires that can fit between the rows and still carry the load is a challenge; e.g., a tractor with split duals for 30 in. (750 mm) rows would likely need split triples for the narrower row spacing. This results in four rows with tire traffic on both sides. An option with 15-in. rows is to leave 30 in. spaces for tractor tires. Another is to keep the wide tires, realizing that for any operations after the crop emerges some damage will occur to the plants driven over. This last option may be better than the wide skip rows because of poor weed control in the unshaded space. Even a very low yield from the plants driven over is better than no yield (and weed problems) from a skip row.

All field equipment needs to cover multiples of the same width. Lighter implements, such as a sprayer or rotary hoe may cover double or triple the width of the planter or drill. The combine or cotton harvester might be one-half, or in some cases one-third, the planter width.

Break long fields in the middle for crop hauling unless a grain cart is used for on-the-go unloading. Any trip through

Fig. 3 The tractor and grain cart (and a sprayer) all have single tires spaced 10 ft. on centers, matching the combine.

the field should continue to the end, or to a cross road, instead of turning around a fraction of the way through.

PLANNING AHEAD

Adopting controlled traffic is not a simple change, but rather a transition that can take several years to complete. Consider controlled traffic in all major machinery buying decisions. Selecting wheels and tires to avoid running on rows adds little to the cost and can provide immediate benefits. Better yet, design a controlled traffic plan appropriate for your operation. Perhaps tires spaced 120 in. (3 m) would fit a farm with large machinery, and 80- or 90-in. (2 or 2.3 m) spacing would be ideal for a smaller farm. The combine header may define the operating width, with the planter being the same or, perhaps, double the width of the combine. (With a precise controlled traffic pattern, the combine can conveniently harvest half the planter width, centered on guess rows.)

The following are tips to consider when buying new equipment:

Choose a combine with tires that match the row spacing. If standard single tires are too wide, use split duals or tall single tires. Costs vary widely by manufacturer. Some combines require several mechanical modifications to accommodate tire changes, others do not. For ridge till, the maximum recommended tire width is 8 in. (20 mm) less than the row width. For no-till or mulch till, tires could be wider, perhaps 4 in. (10 mm) less than row width, but rows with traffic on both sides may lose yield.

Select a small-grain platform with the same width as the corn head on combines.

Buy a drill with the same width as the planter.

Choose pesticide sprayers and fertilizer applicators that cover the planter width, or double or triple that width.

Match grain cart tire spacings with the combine. Plan to run the cart in the same tracks as the previous pass of the combine. This may require an extension on the combine unloading auger.

An auto-steering system makes controlled traffic much easier. The additional cost may be minimal because auto-steering eliminates the need for row markers and foam markers, e.g., which are quite expensive for wide equipment.

CONCLUSION

Controlled traffic eliminates worries about soil compaction and improves overall farm efficiency and economics. Auto-steering is recommended, especially for large equipment, because it makes a controlled traffic system easier to set up and follow. Controlled traffic systems work with no-till and other tillage systems and with most major crops (corn, soybeans, cotton, wheat, and other small grains).

Abstract

Copper (Cu) is a metallic trace element with two naturally occurring isotopes (^{63}Cu and ^{65}Cu) and is essential for the growth of all life. Cu is naturally present in all soils and is found in excessive and potentially toxic concentrations in mine spoils, in waste products from industrial and agricultural activities, and in some agricultural soils due to historic use of Cu sprays (e.g., Bordeaux mix) for disease control. Cu deficiency occurs in many soils around the world, and the addition of Cu fertilizer is required for productive crop growth.

COPPER (Cu) IN SOILS

The average total concentration of Cu in the earth's crust is estimated to be 70 mg kg^{-1} although levels of $20\text{--}30 \text{ mg kg}^{-1}$ are prevalent in average soils.^[1] Common primary minerals include Cu sulfides, with Cu largely in the positive iodine oxidation state, which dissolve by weathering processes. Secondary minerals of Cu(II) include oxides, carbonates (malachite), silicates, sulfates, and chlorides, most of which are relatively soluble. Cu(II) may substitute for iron (Fe), magnesium (Mg), and manganese (Mn) in an assortment of minerals, especially silicates and carbonates.^[1]

The copper ions (Cu^{2+}) can form strong inner-sphere complexes and are thus immobilized by carboxylic, carbonyl, or phenolic functional groups, even at low pH. Exchangeable and weak acid-extractable Cu represents a small percentage of total Cu in most soils. The bulk of the Cu is complexed by organic matter, occluded in oxides, and substituted in primary and secondary minerals. Organic matter and Mn oxides are the most likely materials to retain Cu in a non-exchangeable form in soils. Alkali extraction techniques that remove organic matter from soils usually release large fractions of the total soil Cu.^[2] The addition of organic matter to soils and biological exudation of organic acids may increase dissolved organic carbon, thus solubilizing Cu from mineral forms, increasing the total dissolved Cu in soil solution,^[3] but predictive models of humic acid binding of Cu in soil solution are generally inadequate.^[4] Overall, Cu is one of the least mobile of the trace elements, maintained in a form sufficiently available to plants but relatively resistant to movement by leaching.^[1]

Free Cu^{2+} in soil solution decreases with increasing pH, reaching a minimum above pH 10. In the absence of organic ligands, Cu speciation is dominated by free

Cu^{2+} and increasingly by carbonate and hydroxy complexes as pH rises above 6.5.^[1] The dissolved organic carbon found in the most surface soils has a strong affinity for Cu, but estimates of the percentage of soluble Cu that is organically complexed can vary widely.

Cu AND PLANTS

Plant uptake of Cu appears to be directly related to the concentration of the free ion, Cu^{2+} , but may also be influenced by the total concentration in soil solution, including organic complexes.^[5] As with most trace metals, it is not known whether Cu is passively absorbed or actively taken up across the root-cell membrane.^[6] Rates of absorption are generally low, on the order of 1 nmol h^{-1} (g root dry weight)⁻¹.^[7] The activity of free Cu^{2+} required in nutrient solution for optimal plant growth is just 10^{-14} to 10^{-16} M .^[5] Cu absorption is generally halted by metabolic inhibitors and uncoupling agents which disrupt the normal transmembrane potential.^[7]

Uptake of Cu is strongly affected by pH: Increasing the concentration of hydrogen ions decreases the absorption of Cu ions by plant roots.^[8] Uptake is also affected by the presence of Ca, and to a lesser extent by Mg, both of which compete with Cu for binding sites at the root plasma-membrane.^[9] The effects of other trace metals on Cu uptake have frequently been seen as inhibitory (zinc), or stimulatory (Mn), but not necessarily under well-defined conditions.^[2]

Cu AS AN ESSENTIAL ELEMENT

Cu is an essential element for plant growth and is a component of many enzymes, including plastocyanin, and thus

is an indispensable prosthetic group in Photosystem 2. Cu-containing proteins are also important in respiration (cytochrome *c* oxidase is the terminal oxidase of the mitochondrial electron chain), in the detoxification of superoxide radicals (superoxide dismutase), and in lignification (polyphenol oxidase). Ascorbate oxidase, which contains eight Cu^{2+} ions, has been proposed as an indicator of plant Cu status, although its relevant biological function has yet to be determined.^[10]

The critical concentration of Cu in shoot tissue for optimal growth does not vary greatly between plant species, ranging from 1 to 6 $\mu\text{g g}^{-1}$ dry weight of young leaf tissue.^[11] Most crops are recorded as having a requirement of 3–5 $\mu\text{g g}^{-1}$.^[11] The average concentration of Cu in plant parts varies with age and with the level of Cu and nitrogen (N) supply. The translocation of Cu to plant shoots increases with an increasing supply of N. In the xylem and phloem saps, Cu is probably complexed by amino acids.^[2] Cu is usually described as having “variable” phloem mobility in plants,^[2] as the re-translocation of Cu from older tissues is regulated by both Cu supply and N status. Lack of a sufficiently long-lived radioisotope makes study of Cu transport and translocation problematic.

PLANT GROWTH ON Cu-DEFICIENT SOILS

Cu deficiency most often occurs on organic soils where excessive leaching has occurred, or on calcareous sands. In general, crops grown on mineral soils with Cu contents less than 4–6 $\mu\text{g g}^{-1}$ or on organic soils with less than 20–30 $\mu\text{g g}^{-1}$ are the most likely to suffer Cu deficiency^[12] although this varies with specific soil type and the crop grown.

Symptoms of Cu deficiency include chlorosis, necrosis, leaf distortion, and terminal dieback and are most evident in new leaf growth. Wilting can also occur, indicating structural weaknesses due to reduced lignification of the xylem elements. These symptoms are not entirely specific to Cu deficiency and can be observed in plants under a variety of stresses. The most profound symptoms of Cu deficiency are those seen in the reproductive cycles of many sensitive species: delay of flowering, and/or reductions in seed and fruit yield as a consequence of sterile pollen or reduced floret numbers. Because these latter symptoms are not observed until maturity or harvest, Cu deficiency is often termed a “hidden hunger.” Rice, citrus, and cassava are sometimes referred to as indicator species that are more sensitive to Cu deficiency but are not reported to require more than 5–6 $\mu\text{g g}^{-1}$ Cu to avoid Cu deficiency. Cereal rye and canola are crops more tolerant of Cu deficiency, requiring only 1–2 $\mu\text{g g}^{-1}$ Cu.^[11]

Cu deficiency in legumes depresses nodulation and N_2 fixation, leading to N deficiencies. Unlike molybdenum and cobalt, there seems to be no specific Cu requirement

for N_2 fixation in nodules beyond that required for plant growth and the production of carbohydrates.^[13]

Cu deficiency decreases polyphenol oxidase activity and thus lignification.^[14] Susceptibility of Cu-deficient plants to pathogenic attack may be increased due to reduced lignification of xylem elements or due to impaired lignification in response to pathogenic invasion (wounding response). The application of Cu to soil, at rates too low to directly affect the pathogen, has controlled powdery mildew in wheat.^[15] It has also been suggested that, where Cu in soils is more than sufficient, the accumulation of additional Cu in roots provides a fungistatic defense against pathogens.^[16] Conversely, where Cu is deficient, roots are more vulnerable to pathogenic invasion.

There are genetic differences in the absorption of Cu by plant roots. Rye is able to take up significantly more Cu from soil than wheat and is thus viewed as being more Cu-efficient. Triticale, the wheat-rye hybrid, inherits the efficiency factor.^[7] Cu efficiency could be a useful trait in breeding crops for regions where soils are commonly Cu-deficient.^[17] However, the mechanism of the efficiency factor is not clear.

PLANT GROWTH ON HIGH-Cu SOILS

As some plant species have adapted to soils of low Cu status, others have evolved tolerance to Cu-toxic conditions. The 16th century author, Agricola, wrote of indicator plants that grow on naturally Cu-rich soils. The natural revegetation of mine spoils has been shown to reflect rapid genetic evolution of Cu tolerance by grasses and other plants.^[14] There seem to be several possible mechanisms of Cu tolerance, although exclusion from shoots is a common feature. The exceptions are a few Cu-accumulator species which may contain in excess of 1000 $\mu\text{g g}^{-1}$ Cu in shoot tissue.^[12] In other Cu-tolerant species, the root compartmentation or immobilization of Cu may be achieved by immobilization in cell walls, by complexation with intracellular proteins, or by removal of Cu to the vacuole.^[14]

With non-tolerant taxa, plant growth is likely to be depressed when Cu concentrations in the whole shoots exceed $\sim 20 \mu\text{g Cu g}^{-1}$. Symptoms of Cu toxicity include poorly developed and discolored root systems, reduced shoot vigor, and leaf chlorosis. Toxicity thresholds (e.g., for a 10% yield reduction) seem to vary widely, probably because of the low translocation of Cu from roots to shoots. Only when roots are overwhelmed by Cu, rhizotoxicity does sufficient Cu to reach shoots to affect growth and function. Other syndromes, such as Fe deficiency, can readily occur as secondary consequences of excess Cu.^[14]

The exclusion of Cu from the shoot protects photosynthetic activity, which is highly sensitive to excess Cu. Photosynthetic electron transport is blocked by high levels of free Cu, at the oxidizing side of Photosystem 2, and at the reducing side of Photosystem 1. Excess Cu supply results

in reduced lipid content and noticeable changes in the fatty acid composition of tomato roots and primary leaves, indicating enhanced activity of enzymes that catalyze lipid peroxidation.^[18]

Concentrated Cu sprays have historically been used to control foliar pathogens, especially in vineyard and orchard crops. These fungicidal sprays often included limestone to reduce their phytotoxicity and to make them more rain fast. The accumulation of Cu in the soils under these crops has not regularly caused Cu toxicity, which indicates the remarkable ability of most plant roots to accumulate Cu, while regulating its flow to the shoots. Both Cu deficiency and toxicity may result in non-specific symptoms of plant stress. Assessment of the Cu status of a soil, or of crop plants, is most accurate when soil type, soil history, and soil and plant analyses for Cu are considered.

Abstract

Humanity is facing a large number of challenges in the 21st century, including population growth and a changing climate. The benefits of cover crops (CCs) are very extensive, and CCs can provide a large number of ecosystem services. CCs can be used to cover the surface soil and reduce the off-site transport of soil particles, nutrients, organic matter, and agrochemicals. This makes CCs key tools for maintaining and/or improving soil quality and soil health and great tools to increase carbon sequestration. They are nutrient management tools that can help scavenge nitrate (NO₃), cycle nitrogen (N) to the following crop, mine NO₃ from groundwater, and increase N use efficiency of cropping systems. CCs will be key soil and water conservation tools that could be used across different worldwide agroecosystems to protect soil and water quality and to help in climate change mitigation and adaptation during the 21st century.

INTRODUCTION

Cover crops (CCs) are key soil and water conservation tools that can be used across a large number of worldwide agroecosystems to protect soil and water quality.^[1] The benefits of CCs are very extensive. CCs can be used to provide a large number of ecosystem services. They are tools that can be used for different objectives to provide positive agricultural and environmental impacts. A typical use of CCs is their use to maintain the soil surface cover to reduce soil erosion potential from wind and/or water. CCs can be used to reduce the off-site transport of soil particles, nutrients, organic matter, and agrochemicals.^[2,3] This makes CCs key tools for maintaining and/or improving soil quality and soil health.

CCs are also excellent tools for nutrient management.^[4] They can help scavenge residual soil nitrate (NO₃), reduce NO₃ leaching, and even mine NO₃ from groundwater, helping to reclaim groundwater. CCs can be used to increase cropping system nitrogen (N) use efficiency to protect water quality.^[1,4] CCs can also contribute to increased populations of beneficial insects, weed management and suppression, and pest management. By serving as biocontrol tools, CCs can contribute

to decreased use of agrochemicals and protect water and environmental quality.^[1,5–7]

CCs can be used as a precision conservation practice to manage spatial and temporal variability to increase conservation effectiveness.^[8] CCs can be one of the practices used with a 7 Rs approach to increase nutrient use efficiency and reduce transport of nutrients off-site.^[9] They can be used as scavenger crops and be one of the conservation/nutrient management tools to increase nutrient use efficiencies spatially. CCs can show spatial variation in the amount of scavenged N as well as in the amount of N cycled to the subsequent crop. There is potential to use management zones and precision information to consider these spatial differences when using CCs to account for different N budgets to increase crop N use efficiency while reducing NO₃ leaching losses to the environment and to protect water quality.^[10]

Summer CCs with limited irrigation can potentially be used to increase yields, crop quality, and nutrient and water use efficiencies while protecting the environment.^[11,12] Similarly, winter CCs can also contribute to protection of the environment by reducing the transport of nutrients off-site, and for some cropping systems, they can contribute to increased yields and nutrient use efficiencies.^[4,13] However, summer or winter CCs or CCs in general, independent

of the time of planting, could also potentially contribute to reduced yields of the subsequent crop.^[4,12,13] This could be due to an allelopathic effect, nutrient and water availability, length of the CC season, or a potentially shorter growing season of the subsequent crop, among other possibilities.^[4,12,14] The growing season of the grain (e.g., corn and soybean) may not provide enough time to plant the CC. The user of the CCs needs to evaluate what CC to use and how to manage the CC to avoid potential negative impacts.

There are several factors that can contribute to a negative impact; one of them is incorporation of a CC that has a high carbon-to-nitrogen ratio into the rotation, which could potentially immobilize available N for the subsequent crop, having a negative impact on yields. A CC could use available water stored in the soil profile, reducing available water for the subsequent crop and negatively impacting yields, especially for cropping systems grown in drier climates. Time needed for seeding and establishment of the CCs and for killing and incorporating the CC and preparing the land for the following crop could potentially shorten the growing season, also impacting yields. Fortunately, there are different management practices that can be used to help CCs avoid impacting, or even help them increase, the yields of the following crop while providing a large number of ecosystem services.^[13]

Leguminous CCs such as vetch can be used to add N to a system, since they can fix atmospheric N. Non-leguminous grain CCs such as winter cover rye can be used to scavenge residual soil NO₃ from the deep layers of the soil profile. There are different management strategies to use CCs under different management systems such as no till, minimum tillage, and conventional tillage systems.^[13] CCs can be grazed, harvested for hay, used as mulch or incorporated as a green manure.^[13] CCs can be killed earlier when they have a lower carbon-to-nitrogen ratio or can be killed at a later date to let the CC increase the amount of biomass before it is harvested, or incorporated as a green manure, or left over the surface to make a mulch.^[1,5,13]

One of the hardest management problems to overcome may be the available water used by a CC under a drier system.^[14] In general, the benefits of CCs are so numerous that nutrient managers, conservation practitioners, and others use them as tools to increase nutrient use efficiencies; reduce off-site transport of soil particles, nutrients, and agrochemicals; recover soil NO₃-N from the soil profile and cycle to the next crop; improve soil, air, and water quality; and reduce pests and weeds. The potential of CCs to improve yields is one reason CCs are a key soil and water conservation practice.^[1,5,13] Fortunately, for the majority of cropping systems, management can potentially be used to minimize the potential negative impacts of CCs on yields by using the right CC for the right crop situation for a given combination of soil, weather, and cropping system.^[13] CC management is essential to provide all the benefits of CCs while maintaining and/or increasing yields of the subsequent crop.^[13]

CONSERVATION OF WATER QUALITY

CCs can be one of the tools to apply the “right product, right rate, right method, right practice, right place, right scale, and right time: the 7 Rs of nutrient management and conservation.”^[9] In a 7 Rs approach, using a CC as a scavenger crop in a rotation we can apply the right product (fertilizer), at the right fertilizer rate, with the right method of fertilizer application for the crop. CCs could be the right conservation practice to scavenge NO₃ and reduce erosion potential. Considering spatial variability, a leguminous CC could be planted in some areas of the field with lower leaching potential, whereas a non-leguminous CC could be planted in the other areas of the field with a higher leaching potential, thus applying a conservation practice at the right place, and at the right scale of conservation practice by applying the CCs across the whole field. It will be necessary to apply both the fertilizer and the conservation practice at the right time. CCs could be planted right after harvesting the crop to maximize the potential of the CC to be used as a catch crop to recover the residual soil NO₃ while reducing the potential for erosion. Summer or winter CCs could be used to apply the right conservation practice at the right time.

CCs can have a significant impact on conservation of water quality across the United States.^[1,5] Delgado et al.^[11]

Reported on the potential regional impacts of CCs on conservation of groundwater quality. CCs can potentially be used to minimize NO₃ leaching to groundwater and even mine NO₃ from groundwater, serving as a reclamation tool.

Kladivko et al.^[15] reported on the positive impacts of CCs on water quality of the Mississippi River watershed. The Mississippi River basin contributes to loss of NO₃ to the Gulf of Mexico and to the hypoxia problem in the Gulf of Mexico. Kladivko et al.^[15] discussed the potential adoption of CCs to reduce NO₃ leaching from the Midwestern United States.^[15,16] Kladivko et al.^[15] reported that CCs can have significant positive impacts on water quality across Ohio, Indiana, Illinois, Iowa, and Minnesota. Their analysis of 10 representative counties across these five states showed that from 34% to 81% of the agricultural land planted to corn and soybean rotations could use fall-planted winter cover rye to reduce NO₃ leaching to the Mississippi River by 20%. The winter cover rye could be established with overseeding at main crop maturity in continuous corn and corn-soybean systems on tile-drained lands managed with no-till, spring-till, or fall-till that could be transitioned to spring tillage.^[15] Winter cover rye was one of the CCs reported to recover NO₃ from deep in the soil profile, reducing NO₃ leaching and mining NO₃ from groundwater.^[10] Modeling tools such as NLEAP-GIS 4.2 (Nitrogen Loss and Environmental Assessment Package with GIS Capabilities) and RZWQM (Root Zone Water Quality Model) can be used to assess the benefits of CCs across regions.

CONSERVATION OF SOIL QUALITY

CCs can contribute to conservation of soil quality and soil health.^[6] A key way that CCs contribute to soil health and quality is by reducing erosion. Raindrops impacting a bare soil surface can contribute to the breaking down of aggregates and loosening of soil particles, facilitating their movement in surface water runoff. As water flows over the soil surface, it can also gain energy and increase the kinetic force to dislodge more particles and transport more soil particles off-site. By covering the soil surface with CCs, the plant biomass intercepts and reduces the force of raindrops. The CC biomass that covers the surface slows down the water runoff, reducing its force and velocity as it moves across the surface, contributing to protection of the soil. CC protection to slow down water movement is especially important in those areas of the field with steeper slopes where water may flow downhill and there is more susceptibility to erosion. The belowground root system is also important and can help stabilize the soil and hold it together. Another pathway for surface transport is wind erosion, which can also contribute to the movement of fine particles out of the soil. CCs that cover the soil surface can also protect against wind erosion forces; reducing the off-site transport of soil particles, nutrients, and soil organic matter; and contributing to conservation of soil quality and soil health.

CCs can contribute to increased carbon sequestration and improved soil quality and soil health.^[6,13,17] Increases in carbon sequestration from CCs contribute to improvements in soil quality and health with greater nutrient cycling, more soil aggregates, improved water holding capacity, and higher cation exchange capacity.^[6] CCs also have positive impacts on soil biology, increasing the diversity of microorganisms.^[6]

CONSERVATION OF AIR QUALITY

CCs protect air quality by reducing wind erosion and the aerial transport of soil particles and agrochemicals that may be tied to this process. Emissions of greenhouse gases are also reported to negatively impact air quality. One of the important greenhouse gases is nitrous oxide (N_2O), the emissions of which contribute to the greenhouse effect and climate change. CCs could potentially contribute to reduction of N_2O emissions.^[18] A meta-analysis of the use of CCs found that non-leguminous CCs reduce N_2O emissions. Although leguminous crops have the potential to increase N_2O emissions, when N_2O measurements were monitored over the whole year, on average the impacts of CCs on N_2O emissions ranged from negligible to a small increase in N_2O emissions.^[18] It is also important to point out that leguminous CCs could fix atmospheric N, which can be cycled to the next crop, reducing the amount of N fertilizer applied to the next crop. CCs also reduced the

potential for NO_3 leaching, reducing indirect emissions of N_2O . The data suggest that there is potential to use CCs to reduce N_2O emissions.^[18]

Delgado, Del Grosso, and Ogle^[19] conducted an analysis of the N losses from inorganic fertilizer versus the N losses from CCs' N content using published ^{15}N data and simulation modeling. Delgado, Del Grosso, and Ogle^[19] found that the average percentage of N loss (N that is not found in the following crop or in the soil profile) is 33%. The data from the ^{15}N -labeled CC residue showed that only 10% was lost from the system. The average amount of N fertilizer lost from the system is 66% greater than the N lost from the CC. So the losses via N_2O emissions from the CC were assumed to be lower than those from the fertilizer when comparing losses from the ^{15}N -labeled N fertilizer versus losses from the added ^{15}N -labeled CC residue. This was in agreement with model simulations of the ^{15}N -labeled N fertilizer and of the ^{15}N -labeled CC that showed lower N_2O emissions with the CC system. There is an opportunity to use CCs as a climate change mitigation and adaptation practice.^[19]

CONCLUSION

CCs are great tools to improve soil quality and health^[6] and great tools to increase carbon sequestration.^[17] They are nutrient management tools that can help scavenge NO_3 , cycle N to the following crop, mine NO_3 from groundwater, and increase N use efficiency of cropping systems. N cycling from CCs is more efficient than from inorganic N fertilizer, and CCs act like a slow-release fertilizer, with 66% lower losses than the losses from inorganic N fertilizer.¹⁹ CCs can be grazed or harvested for hay, used as a mulch, or incorporated as green manures. CCs can contribute to suppression of weeds and pests.^[7] CCs are excellent tools for soil and water conservation and climate change adaptation and mitigation. To maximize these positive effects of CCs and to avoid any negative impacts on yields, CC users need to determine the right CC for the right crop rotation and how to manage the CC. In other words, "There is a need to use the right cover crop or cover crop mixture, select the right time to plant and harvest or kill the cover crop, and apply the right cover crop management practices at the right location, to increase the benefits of cover crops (the 4Rs for cover crops)."^[20]

Abstract

Crop evapotranspiration is an important parameter in research of water conservancy, meteorology, soil science, natural geography, and other related disciplines and fields. The system for measuring crop evapotranspiration mainly consists of three parts: test pit, lysimeter, and standardized evapotranspiration measurement test field. It is characterized by the following features: 1) two large weighing lysimeters are installed, not only to realize normalized automatic measurement and observation, but also to conduct data correction by measuring a large area with high precision; 2) the test pit and lysimeter cylinders are installed with a high-precision system for the measurement of soil water content, soil water potential, and soil temperature via the water balance method can be employed for the self-correction of measured data; 3) the large-size test pit groups and high-precision lysimeters are used to conduct a comparative study on different evapotranspiration measurement methods and to perform a mutual verification between the field measurement of crop evapotranspiration and by other methods; and 4) relatively large numbers of test pit groups and rainproof systems are used to conduct the evapotranspiration test on different moisture, nutrient gradients, and different crops and to combine the evapotranspiration measurements with the meteorological data to determine the locally representative and important parameters such as crop water requirement, crop coefficient, and irrigation system.

INTRODUCTION

Crop evapotranspiration refers to the sum of the soil/watering surface evaporation between plants and the transpiration of plants.^[1] Generally, four methods are employed to measure the evapotranspiration of dry land crops. This involves a combination of the lysimeter method, the pit checking method, and the field measurement method, which follow the water balance principle to measure evapotranspiration of crops, and the instrument measurement method. The lysimeter method measures the evapotranspiration of crops cultivated in soil tanks through weighing, and the pit checking method and the field measurement method both use specially built test pits or fields to monitor the water balance equation of the soil. The instrument measurement method introduces systems such as the eddy covariance and Bowen ratio system to measure the evapotranspiration by applying the principles of energy balance and water vapor diffusion.

Of the four methods, the lysimeter method has high precision and can rapidly and accurately reflect the variation process of crop evapotranspiration. However, the design of lysimeter measurement and control system and the corresponding means of measurement exert a

significant influence on the results. The pit checking method has a relatively high precision and is used to measure evapotranspiration at weekly or monthly time scales, in which case the selection of the number and form of test pits is of great importance. The field measurement method is carried out in the field by the water balance method, therefore the test fields must be representative of the growing conditions, as the accuracy of the results measured under restricted conditions in a small area cannot be guaranteed.^[2] The field instrument measurement method requires uniform and open test fields and can be subject to the influence of surrounding environment.

Establishing a precise crop evapotranspiration measurement system is of great importance for studying the water consumption law and the spatial transformation of precipitation (irrigation water) to soil water, underground water, plant water, and subsequently to atmospheric water.

1. Crop water requirement measurement system using a lysimeter

The lysimeter is a large-size vessel that is loaded with soil, placed in the fields or under the ground, and exposed on the surface or covered with plants to simulate the

growth environment of the field to measure the evapotranspiration of growing crops or the evaporation of uncovered soil. In essence, the device measures the transformation of water bodies under restricted 3-D boundary conditions. The system consists of three parts, the measurement apparatus, data transmission, and terminal display. The measurement apparatus is constituted of soil, steel cylinder, weighing system platform, weighing system, weighing sensor, and displacement sensor. The data transmission part is constituted of the front-end amplifier and data conversion module. Finally, the terminal display part is constituted of lysimeter host, backup power source, and computer bundled software.

a. Lysimeter measurement principle

The water balance equation of the soil column of the lysimeter is calculated as follows:

$$\Delta S = P + I + Q - \Delta R - ET \quad (1)$$

ΔS represents the variation of water stored by the soil, P represents the precipitation, I represents the irrigation, Q represents the underground water flow, ΔR represents the net surface runoff, and ET represents the evapotranspiration. All of the above variables adopt millimeter as their unit.

For a lysimeter, generally ΔR can be neglected, so Eq. (1) can be simplified into:

$$ET = P + I - Q - \Delta S \quad (2)$$

P and I can be directly measured with a rain gauge and water meter. ΔS represents the increase in moisture after precipitation (or irrigation) or the loss of moisture caused by evapotranspiration. Given that this can be a difficult variable to measure, a high-precision weighing system has been developed for the measurement of ΔS .

Q represents the water supplied into and drained out of the soil column through the water supply/drainage system of the lysimeter. In cases where the underground water level remains constant, the water supplied into the soil column is the replenishment of soil water by underground water (E_g) and is represented by $E_g = Q$. The water drained out of the soil column is the replenishment of underground water (R_g) and is represented by $R_g = Q$. When the underground water levels vary in the field, a certain amount of water must be supplied or drained from the soil column to ensure that the water level of the instrument and the fields are consistent. In these cases, the replenishment of soil water can be calculated indirectly.

If the underground water level has risen by ΔH :

$$E_g = Q - a \cdot \Delta H \quad (3)$$

If the underground water level has declined by ΔH :

$$E_g = b \cdot \Delta H - Q \quad (4)$$

Fig. 1 Schematic diagram of the weighing mechanism principle.

Where a and b are the coefficients measured in the water absorption and dehydration tests. If $a = b = \Delta Q$, then ΔQ represents the variation of water content of underground water levels and can be measured with the moisture meter.

b. Weighing system principle

Fig. 1 depicts the weighing system principle. It is clamped by two square bars in the middle of the steel wire rope and works in concert with two tapered iron blocks and the balance arm to create the working state. When the balance arm is at the horizontal level, the steel wire rope produces a vertical dislocation (datum zero). When the weight of the soil mass varies, the balance arm swings up and down to produce a variation of swing angle, which is then transformed into linear displacement via the rigid link mechanism. Following that, a high-resolution displacement sensor is used to measure the variation of displacement, thus measuring the weight variation of soil box.

c. Data collection system principle

The signal amplifier can collect the signals of the displacement sensor and percolation sensor, amplify them into digital signals, and transmit these signals to the data collector via RS485. The data collector adopts single-chip microcomputer as CPU control board and uses Flash ROM as data-recording medium. This system can continuously store 30,000 groups of data, each of which consisting of displacement, percolation, temperature compensation, as well as the corresponding time point of the measurement. The host computer can obtain data from the data collector via RS-232 on a real-time or archival basis and compile them into data, curves, or sheets in standard formats, which are then to be analyzed and filed by the experimenter.

There is a linear relationship between the weight variation of the lysimeter's soil box and the displacement variation of the displacement sensor. The automatic data

Fig. 2 Evapotranspiration variation curve.

collection system consists of signal amplifier and data collector. After obtaining the displacement variation through a group of displacement sensors, the coefficient obtained through calibration is then used to calculate the weight variation of the corresponding soil box, which corresponds to the variation of the water storage.

A percolation sensor is installed at the bottom outlet of the soil box to measure the variation of percolation. The evapotranspiration is calculated from water storage and percolation. The evapotranspiration is obtained after subtracting the variation of percolation from the variation of water storage. As can be seen from Eq. (2), the actual transpiration of the system includes precipitation and irrigation; see the measured figure lines in Fig. 2.

2. Crop evapotranspiration and irrigation water circulation measurement system of test pits

The system is built with a total of 44 test pits, 4 of which are bottomless test pits. The test pit system consists of standardized test pits, data collection corridor, and automatic mobile rain shed, occupying a total construction area of 640 m² and is installed with underground soil solution collection device and time domain reflectometry (Trime-IPH) TDR soil moisture measurement device (see the upper and lower parts of test pits in Fig. 3).

Each test pit has an area of 2 × 3.33 m² and a depth of 3 m, is enclosed on all sides with reinforced concrete, and provided with waterproof treatment. The wall of the test pit

Fig. 3 Aboveground and underground parts of test pits.

exposed above the ground has a height of 8 cm. The soil is backfill soil, and the bottom of the test pit is paved with an inverted filter layer 20 cm in thickness and consisting of sand and gravels. The base is provided with a lateral drain-pipe, connected with the drainage collection system. Soil backfilling must be done in layers that are in strict accordance with the unit weight of the original soil layers. The soil in the bottomless test pits must be undisturbed soil, as this is a key link in ensuring the representativeness of the test results of these test pits. For the purpose of precipitation control, mobile rainproof facilities are installed above the test pits. Each test pit is installed inside with a TDR water content measurement tube 2.5 m in depth, used for regular or irregular soil moisture measurement. The outer wall of each test pit is also installed with eight soil sampler bottles of different depths and with 13 automatic soil moisture measurement systems. The moisture variation inside test pits is obtained through calculating the difference between the soil water contents measured twice in succession.

3. Field measurement of standardized crop evapotranspiration

Based on the test pits and the lysimeters, a standardized crop evapotranspiration measurement field of 15,000 m² in area is built. Besides being used for the basic observation of field evapotranspiration, the field is also installed with an eddy covariance system (also used as automatic meteorological station), Bowen ratio system, and soil moisture measurement equipment, which together constitute a complete and high-level field crop evapotranspiration measurement system.

The open-type carbon dioxide (CO₂) eddy covariance system (LI-7500A; Fig. 4) adopts the micrometeorological turbulent eddy motion covariance method and can automatically measure and store near-earth air layer measurement of parameters such as 3-D wind velocity fluctuation, temperature fluctuation, H₂O fluctuation, CO₂ fluctuation, CO₂ flux, water vapor flux, sensible heat flux, air momentum flux, energy exchange flux, frictional wind velocities, and other micrometeorological characteristic variables between the ground surface and the atmosphere during their interactions, with the purpose of determining the fluxes of CO₂ and H₂O. The distance between the eddy covariance system and the test area boundary ranges between 375 and 1,700 m, meeting the requirement that the ratio of the fetch length to the installation height should be greater than 100:1. Through measuring the fluctuations of vertical wind velocity and water vapor density,

Fig. 4 The eddy covariance system.

the eddy covariance method can directly observe the crop evapotranspiration from a meteorological perspective and conduct long-term, continuous, nondestructive, and fixed-point monitoring over ground surface ET. Compared with the lysimeter method and other methods, this method features a relatively short measurement step size, and its equipment can obtain a lot of high-temporal resolution ET and environmental variation information within a short period of time. This system can also be contrasted with the Bowen ratio system in the test field for further measurement and studies.

The crop evapotranspiration monitoring can generate systematic and multiscale measurements of crop evapotranspiration that fully takes into account the influence of climate, soil moisture status, topography, crop, and other factors on the measurement precision. Through modifying various observation and measurement methods and fully applying computer technology and sensor technology, there has been an extremely significant increase of measurement precision, integrating several measurement methods in a convenient, rapid, and labor-saving manner to generate measurements for studies of crop evapotranspiration on different scales.

Crop Management: Seasonally Frozen Soil

Brenton S. Sharratt

Land Management and Water Conservation Research Unit, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Pullman, Washington, U.S.A.

Abstract

The thermal regime of soils during winter and spring can have a profound influence on civil engineering designs, watershed hydrology, and agricultural productivity. For example, alfalfa (*Medicago sativa* L.) and winter wheat (*Triticum aestivum* L.) can die as a consequence of heaving as soils freeze and thaw. Heaving may lift plants above the soil surface where there is a greater risk for exposure of crown and root tissues to lethal temperatures of about -20°C . In addition, the presence of frozen layers within the soil profile can impede water infiltration during snowmelt and rain events as well as retard drainage as the soil thaws in spring. Drainage, as well as soil temperatures, can also affect the timing of field operations such as planting. Agricultural productivity, therefore, depends on moderating soil temperatures during winter and rapidly thawing the soil profile in spring. Soil temperature and thaw can be regulated to some extent through crop residue and soil management.

INTRODUCTION

The thermal regime of seasonally frozen soils is dependent on the interrelated processes of heat and water transfer at the soil surface and within the soil profile. The processes of heat and water transfer at the soil surface are governed by atmospheric conditions and physical properties of the soil at the soil–atmosphere interface. Atmospheric conditions such as air temperature, humidity, solar radiation, wind, and precipitation influence the energy available for processes such as soil heating and evaporation. In cold regions, snow cover will modify the atmospheric conditions at the soil surface. Texture, density, water content, and ice content are important physical properties of soils affecting the transmission of heat through a frozen soil. Ice formation typically occurs in soils at temperatures below 0°C due to capillary and adsorption forces that reduce the free energy status of water in soils. The process of freezing and thawing affects the quantity of heat transmitted through soils since heat (334 J g^{-1}) is liberated as pore ice freezes and must be absorbed to melt pore ice. The process of ice formation and melting requires nearly 100 times the heat (4.2 J g^{-1}) expended in warming or cooling water by 1°C . Thus, heat transfer processes in soils are influenced by phase transitions that occur as soils freeze and thaw. Atmospheric conditions and physical properties of the soil at the soil–atmosphere interface can also be modified by the quantity and orientation of crop residue on the soil surface as well as by the depth and type of tillage.

CROP RESIDUE

Crop residues can mitigate soil erosion, protect plants from winter temperature extremes, and provide a favorable

environment for seed germination in the spring. Residues act as a barrier to heat and water transfer between the atmosphere and soil, thereby retarding heat loss from the soil during winter and hindering the warming of soil in spring. This thermal retardation is shown in Fig. 1 for a clear day in late autumn, winter, and spring. On warm autumn and spring days, soil without residue cover was warmer during the daytime and cooler at night than soil with residue cover. On cold winter days, however, soil with residue cover remained warmer throughout the day than soil without residue cover.

Residue management alters the amount and orientation of crop residue on the soil surface. Various techniques employed in managing crop residues include cutting stubble at various heights, burning residue, removing residue from the seed row, and altering the color of the residue. The winter thermal regime of soil can be dramatically affected by the height of stubble, especially in regions where strong winds redistribute snow. Taller stubble traps more snow and thereby provides additional insulation to the soil that can reduce frost penetration, hasten thawing of the soil profile, and elevate soil temperatures (Table 1). Burning crop residue in autumn or spring can hasten soil warming in the spring by removing residue from the soil surface and temporarily elevating soil temperatures by 100°C or more.^[1] These high temperatures, however, are only sustained for a few minutes during the burn and near the soil surface. In addition, crop residue can be removed along the seed row to bolster soil temperatures during spring. Daily temperatures can rise by 2°C as the width of the band increases from 0 to 20 cm but are unaffected by bands greater than 20 cm.^[2] Residue color can alter soil temperatures, but only on clear days without snow cover. Daily temperatures can be as much as $1\text{--}2^{\circ}\text{C}$ higher for soils covered with black than with natural straw.^[3]

Fig. 1 Temperature at 1-cm depth of a soil with and without soybean (*Glycine max* L.) residue cover and without snow cover on a clear day in late autumn, winter, and spring near Morris, Minnesota.

SOIL MANAGEMENT

Tillage is used to prepare a seedbed, alter the physical properties of soil to curtail erosion, and optimize the thermal regime of the seed zone. In cold regions, methods are

Source: From Sharratt.^[4]

sought that roughen, darken, and reduce the amount of residue on the soil surface to hasten soil warming in the spring. No tillage is advocated to conserve the soil resource, but this method often retards warming of the soil. Other methods such as strip tillage, ridge tillage, chisel plow, and moldboard plow are alternatives to managing the soil thermal regime. Strip tillage is accomplished in autumn or spring by cultivating in bands, thus resulting in a residue-free band. Little is known concerning spring temperatures achieved using strip tillage, but temperatures may be similar to those of residue-free bands. Ridge tillage can dramatically affect soil temperature in cold regions.^[4] Daily temperatures on a southerly slope can be elevated as much as 2°C over those on a level surface and 5°C over those on a northerly slope (Table 2). Spring soil temperatures are generally higher for moldboard and chisel plow owing to the rougher, darker, and smaller amount of residue on the soil surface compared with other tillage methods. Daytime temperatures can be 15°C higher, while nighttime temperatures can be 5°C lower, for moldboard plow than no tillage.^[5]

Crop and soil management practices that retard heat loss from soils in winter also slow the warming of soil in spring. Discovery of new residue management or tillage techniques that enhance soil warming during winter and spring is essential to the viability of agriculture in cold regions. These techniques will be identified only by improving our understanding of those physical properties of residue and soil that influence heat and water transfer between the soil and atmosphere.

Crop Plants: Phosphorus Availability

Bettina Eichler-Löbermann

Institute of Land Use, University of Rostock, Rostock, Germany

Ewald Schnug

Institute for Crop and Soil Science, Julius Kuhn Institute (JKI), Braunschweig, Germany

Abstract

The economical use of phosphorus (P) is a key issue for sustainable agriculture because its natural resources are among the first to be depleted in a predictable time span. P supply to crop plants is generally assured by fertilizer application; however, less attention has been paid to the active energy supply and adaptation mechanisms, enabling the plants to mobilize P in soils. This entry focuses on the P efficiency of crop plants and possibilities to improve the utilization of P in agriculture. In this context, special attention is given to catch crops as a means of improving the P supply of the following main crops.

INTRODUCTION

Plants respond to their soil environment and are able to influence the nutrient availability in the rhizosphere.^[1] Among others, there are mechanisms that enable plants to acquire P from the soil. Some of these mechanisms are specific for P, such as the excretion of phosphatases by the roots.^[2] Others affect a wide range of nutrients, such as the development of root hairs and the enhancement of the root to shoot ratio.^[3]

IMPROVEMENT OF P EFFICIENCY

Although soils may contain 400–1000 kg/ha P in total, the amount of plant available P in soil is usually low. Up to 90% of the total soil P is found in the non-labile pool, as a result of immobilization into organic and inorganic components.^[4]

Improvement of P efficiency is accomplished by either a raise of the P uptake or a better utilization of the existing P in the plant. Crop plants have different strategies to influence the P uptake. Some plants adapt to low-P soil by changing their root morphology, while others excrete P-solubilizing compounds.^[5] There are major differences between plant species (Table 1), but even genotypes within the same species may differ in their P efficiency.^[6,7]

Under P-deficient conditions, plants usually increase their root system in relation to the shoot. Because of this increased root to shoot ratio, the nutrient need and the nutrient influx of the single root decrease. Especially monocotyle plants such as maize (*Zea mays*) and grass are known to have a large root length and root surface. Thus, they can utilize a greater soil volume, which is of vital importance for P utilization, as it has a low mobility in soil.^[3,8]

Plant root exudates mainly consist of a complex mixture of amino acids, organic acids, organic and inorganic ions, sugars, vitamins, nucleosides, enzymes, and root border cells, which have major direct or indirect effects on the acquisition of mineral nutrients required for plant growth.^[9–11] Besides the acidifying effect of the excreted organic acids such as citric and malic acids, there are also chelating effects. Acidification of the soil enhances the solubility of P in basic soils, while the chelating compounds bind cations and thus release P from primarily not available Ca, Fe, and Al phosphates.^[12]

The capacity to excrete organic acids is pronounced for some Proteaceae, which do not form mycorrhizal associations but have proteoid roots. Under P deficiency, lupine (*Lupinus albus*) excretes much more malate and citrate from its proteoid roots than under sufficient P supply.^[13] Oilseed rape (*Brassica napus*) has a higher P uptake from rock phosphate than sunflower (*Helianthus annuus*) because of higher excretion of malate and citrate.^[14] For corn, regarding the root excreted sugars, Schilling et al.^[5] found that under a lack of P the portions of pentoses excreted increase while the amounts of hexoses and sucrose decrease.

Root exudates also contain chemical molecules that control the development of plant–fungal symbiosis, as they provide signals that alert the mycorrhizal fungi to the presence of a host plant.^[10]

Mainly soluble inorganic soil P can be taken up by plants. Therefore, the organic P compounds have to be mineralized into inorganic P forms to become available. This process is promoted by phosphatases. Acid and alkaline phosphatases are known, which occur in dependence of the pH value of soils.^[15] Acid phosphatase in soil originates from many sources, including plant root exudates, fungi,

^cField experiment (loamy sand), average of six sampling dates, from spring 1999 to autumn 2001.

^dField experiment (loamy sand), average of P uptake of main crops (summer oilseed rape, summer barley, and summer wheat) from 1999 to 2001.

mycorrhizal fungi, and bacteria. Alkaline phosphatase is produced by soil microorganisms and soil fauna, whereas higher plants are devoid of alkaline phosphatase.^[16] In a pot experiment, the highest activity of acid phosphatase was found in soil under serradella (*Ornithopus sativus*), amaranth (*Amaranthus hypochondriacus*), and maize; by far the lowest activity of acid phosphatase was found in soil under ryegrass (*Lolium westerwoldicum*) and phacelia (*Phacelia tanacetifolia*) (Table 1).^[17]

The soil pH is important for the P solubility, which is higher in neutral soils than in acid or alkaline soils.^[11] Plants affect the soil pH not only by the excretion of organic acids but also by the amount of inorganic ions absorbed by roots.^[18] Plant uptake of anions in excess of cations often causes the secretion of HCO₃[−], which leads to increased pH values. On the other hand, the uptake of cations in excess to anions can cause roots to exude H₃O⁺ and lower the pH value. This could be shown for phacelia (Table 1).^[19]

Catch cropping has a positive influence on soil fertility and can reduce nutrient losses from soil.^[20,21] Furthermore, plants used as catch crops or inter crops can improve the P supply of the following main crops directly by increasing the plant-available P amount in soil or indirectly when used as green fertilizers.^[22] The organic bound P in catch crops becomes available to the main crops after decomposition. In different experiments, catch crops, such as phacelia and serradella, were found to mobilize P in soil. They substantially increased the P content in soil and soil solution in P poor soils, and the P uptake of the main crops was enhanced (Table 1). On P-poor sandy soils, buckwheat (*Fagopyrum*

esculentum) was found to have a high P uptake.^[19] In a pot experiment, a green fertilization with phacelia increased the P uptake of the following maize more than a fertilization with triple-super P or manure.^[19] However, catch cropping does not replace the P fertilization, but it should be seen as an opportunity to improve the utilization of P.

The active mobilization of P sources by plants is an important factor to counteract the loss of P solubility by fixation and adsorption and thus a source of energy for high P utilization. The mobilization of P in soil can contribute to save commercial fertilizers. Green fertilization with catch crops that have a high P uptake efficiency may help to improve P supply of the main crops.

Abstract

Crop residue management is a general term used to describe tillage management practices that leave a significant portion of the soil surface covered with the previous crop's residue to reduce wind and water erosion. Residue management practices include no-till/strip-till, mulch-till, and ridge-till. Although all residue management practices can favorably impact soil, water, and air quality, they will vary in the degree of this benefit, depending on the amount of soil disturbance, surface residue cover, soil, and climate. This entry focuses on no-till/strip-till because it provides the greatest beneficial environmental impacts compared to the other residue management practices.

INTRODUCTION

Residue management practices are defined as follows:

1. No-till/strip-till: Managing the amount, orientation, and distribution of crop and other plant residues on the surface year-round while growing crops in narrow slots or tilled or residue-free strips in soil previously untilled by full-width tillage implements.
2. Mulch-till: Managing the amount, orientation, and timing of crop or other crop residues on the soil surface year-round while growing crops where the entire field surface is tilled before planting.
3. Ridge-till: Managing the amount, orientation, and distribution of crop and other plant residues on the soil surface year-round while growing crops on preformed ridges alternated with furrows protected by crop residue.

CROP RESIDUE MANAGEMENT SURVEY DATA

Conservation tillage was used only on 4 million ha or 3% of all cropland acres in the United States in 1970.^[1] The decade of 1990s saw a pronounced increase in the adoption of conservation tillage. It increased from 29.6 million ha or 26% of all annually planted cropland acres in 1990 to 43.8 million ha or 36.3% of all annually planted cropland acres in 2000 (Fig. 1). This increase of 14.2 million ha in conservation tillage acres has come almost entirely from the no-till category. Soybeans and corn accounted for 75% of all no-till acres in 2000. During the 1990s, no-till experienced a 210% increase, growing from

6.8 million ha to 21.1 million ha. Ridge-till and mulch-till have remained basically unchanged during this same time period. No-till growth was more pronounced from 1990 to 1994 when it averaged a 2.2 million ha increase every year.^[2]

SOIL, CLIMATE, AND CROP RELATIONSHIPS

The successful adoption of conservation tillage and no-till, in particular, is dependent on the soil type, crop rotation, and climate of a given region. No-till is widely adopted in an area only if the local management strategies minimize risk and maintain or increase yields. Some of the key soil properties, which may influence no-till adoption, include soil drainage, soil texture, slope, and organic matter levels. Key climatic factors include total rainfall, rainfall distribution, temperature, and length of growing season. Crops vary in their adaptability to conditions typically found in a no-till environment. Commonly, a no-till seedbed will be cooler and will have a higher moisture level than the soil previously tilled, which may be an advantage or a disadvantage to achieving the desired stand. In addition, the crop rotation is more important in a no-till environment. Rotating crops minimizes potential allelopathic effects and reduces insect, weed, and disease pressure.

ENVIRONMENTAL BENEFITS

Key environmental benefits of residue management practices, although site specific, generally include erosion

Fig. 1 Conservation tillage adoption in the United States, 1990–2000.

Source: From CTCIC.^[2]

reduction, improved soil, water, and air quality, and reduction in sediment. In addition, other agronomic benefits include improved moisture conservation, reduced soil compaction, improved soil structure, and reduced surface crusting. This entry will briefly discuss the key environmental benefits of crop residue management practices, including soil erosion reduction and soil, water, and air quality improvements.

Soil Erosion Reduction

Crop residue left on the soil surface significantly reduces each of the water erosion processes, including soil detachment, transport, and deposition. When rain falls on a bare soil surface, soil particles are dislodged from soil aggregates by the explosive action of falling raindrops. Surface residue cover intercepts the falling raindrop and dissipates its erosive energy. Surface residue can also form small dams that slow surface runoff. When the surface runoff is slowed, it has a greater opportunity to infiltrate the soil surface. The benefit of surface residue in reducing inter-rill and rill erosion is shown in Fig. 2.^[3] No-till leaves the most surface residue cover of the residue management practices and is the most beneficial of these practices in reducing soil erosion. With no-till, the amount of surface residue cover can approach 80–90% after high residue-producing crops and 30–50% after low residue-producing crops.

Crop residue left on the soil surface also significantly reduces each of the wind erosion processes, including surface creep, saltation, and suspension. The threshold wind velocity required to begin the wind erosion process is higher across surfaces protected by crop residue. Also, crop residue is more effective in reducing wind erosion if it is left standing compared to lying flat. However, in most no-till situations, the orientation of residue is not critical

because large quantities of surface residue are present. With low-residue producing crops, planting crops perpendicular to the prevailing wind and leaving crop residue standing become more important.

Soil, Water, and Air Quality

Sediment is the number one pollutant in the United States.^[4] It not only creates physical problems but also is detrimental to plants, animals, and aquatic species. No-till significantly reduces soil erosion, increases infiltration, improves aggregate stability, and increases organic matter. As a result, the amount of sediment reaching surface water is reduced.

Soil organic matter is probably the most important soil quality indicator. Reducing soil erosion has a direct positive impact on soil quality because the amount of soil organic matter lost through erosion is greatly reduced. No-till can have a significant impact on increasing soil organic matter, while full-width tillage minimizes the opportunity to increase soil organic matter. The largest increases in soil organic matter with intensive cropping result from continuous no-till. If no-till is used 1 year followed by full-width tillage, the increase in organic matter will be limited.^[5] Soil organic matter increases primarily through avoidance of tillage, leaving the root structure undisturbed.^[6] Even with continuous no-till, however, the increase in soil organic matter is a slow process.

Crop residue provides an energy source for microorganisms. They use crop residue for their life processes and return humus to the soil, resulting in an increase in soil carbon. The population of microorganisms in the soil is directly related to the amount of energy or food available. When residue is incorporated in the soil, microorganisms consume it rapidly, leaving little or no energy source available for top-feeding organisms. As a result, the energy

Fig. 2 Approximate effect of residue cover on any day in reducing sheet and rill erosion compared to conventional tillage without surface residue cover.

Source: From Renard, Foster, et al.^[3]

source is quickly depleted, and the number of beneficial microorganisms decreases. When crop residue is left on the soil surface, microorganisms consume it more slowly, remain active for longer periods, and significantly contribute to improving soil humus.^[7]

Nutrients, such as phosphorus, that attach to soil particles are slow to move in the soil profile but can move with surface runoff and sediment. Soluble nutrients that have not infiltrated the soil can move freely in surface runoff. Because residue management practices reduce erosion, improve infiltration, and reduce runoff, they play a key role in reducing the transport of nutrients across the surface and potential contamination of surface water.

Pesticides can present a potential water quality concern similar to nutrients by either moving off target in surface water or attaching to soil particles. However, since residue management practices reduce erosion and surface runoff, these practices help reduce the potential for off-site contamination.

With no-till, herbicides replace tillage for weed control. However, the total amount of herbicides used in comparison to full-width tillage systems is not significantly different.^[8] Herbicide chemistry has changed dramatically providing new crop protection chemicals that are applied in milliliters rather than liters per acre and are less toxic to non-target species. As a result, these new products are considered more environmentally friendly. In addition, biotechnology has made weed control easier, cheaper, and more environmentally friendly for certain crops.^[8]

In addition, biotechnology has helped to facilitate the adoption of no-till with certain crops.

Extensive macropores in no-till, especially if open to the surface, have raised some concern about providing a direct conduit for potential groundwater contaminants. Some macropores, especially earthworm channels, contain large amounts of organic matter along their walls that can absorb some of these chemicals and help retain them in the upper portions of the profile. Earthworm channels also have increased microorganism activity that can significantly increase the breakdown and degradation of chemicals and reduce their potential for groundwater contamination.

Particulate matter of 10 μm (PM-10) in size has been identified as a potential health hazard.^[9] These fine particle sizes can be generated from wind erosion, tillage, and harvesting operations. No-till/strip-till, ridge-till, and mulch-till practices used with high residue-producing crops should provide sufficient residue cover to significantly reduce air quality hazards from PM-10 by reducing wind erosion and tillage trips.

CONCLUSION

Crop residue management practices provide numerous environmental benefits, are economical for growers to implement, and are the most widely used conservation practices in the world. Although increases in no-till adoption in the United States have been the primary reason for

the increase in crop residue management practices in the 1990s, the adoption rate has slowed in the later part of this decade. More emphasis must be placed on the use of continuous no-till if growers and society are to achieve the benefits described in this entry.

Crop Root Response to Temperature: Temperate Zone

Thomas C. Kaspar

National Soil Tilth Laboratory, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Ames, Iowa, U.S.A.

Abstract

Root system expansion is a function of three temperature-dependent processes: growth, development, and orientation. Temperature affects root growth through its influence on root weight, root length, and root diameter. Root development is influenced by the effect of temperature on root initiation and root turnover. Finally, temperature controls root orientation through its impact on the direction of root growth.

INTRODUCTION

In temperate regions, the average temperature of the soil profile rises from winter minimums to summer maximums as the growing season progresses. At the time of planting for most summer annual crops, a temperature gradient has developed in the soil profile with temperature decreasing with depth. As the soil surface absorbs thermal energy throughout the growing season, deeper soil layers become increasingly warmer.^[1] Because temperature influences a wide variety of plant functions, it is not surprising that soil temperature affects root growth in many ways,^[1–5] and that the expansion of crop root systems in temperate regions is limited by cool soil temperatures.^[1,6]

ROOT GROWTH

Root dry weight is the most commonly measured growth parameter. For most plant species, the temperature response of root dry weight follows a typical temperature response curve (Fig. 1).^[1] The optimum, minimum, and maximum growth temperatures of the response curves differ among plant species and among genotypes within species. Generally, crop species that are winter annuals or cool-season species, such as oat (*Avena sativa* L.), rye (*Secale cereale* L.), wheat (*Triticum aestivum* L.), and rape (*Brassica napus* L.), have lower optimum, minimum, and maximum growth temperatures than crops such as cotton (*Gossypium hirsutum* L.) or maize (*Zea mays* L.), which are summer annuals.

Crop root length is an important factor in determining water and nutrient uptake. Root elongation responds to temperature in much the same way as root dry weight (Fig. 2).^[2] Similarly, plant species and genotypes within species differ in their response to soil temperature.

Root length, however, often responds more strongly to soil temperature than does root dry weight. For example, Loffroy et al.^[7] found that cotton taproot length at a root temperature of 17°C was less than 40% of its length at 27°C, whereas root dry weight was 68% of that at 27°C. Presumably, this occurred because the mean taproot diameter was greater at 17°C than at 27°C.

Root diameter along with root length determines root surface area. Additionally, the amount of carbohydrate required for root system expansion is determined by root diameter. Unfortunately, the effect of temperature on root diameter is not clear. Part of the confusion arises because of the differences between mean root diameter of an entire root system and mean root diameter of the roots in a branching order of roots within a root system. Root branching orders are determined by the point of origin of the root. For example, a first-order root originates from the seed, whereas second-order roots originate from first-order roots. Generally, higher order roots have smaller diameters than the lower order roots from which they originate. Thus, an increase in root initiation or branching results in more roots with smaller diameters. If temperature increases root initiation, then mean root diameter of the root system is likely to decrease. Another complicating factor is that root diameters of individual roots tend to decrease as they elongate. Therefore, the generally shorter roots at cooler temperatures would most likely have greater mean diameters than the longer roots grown at warmer temperatures. In summary, the mean root diameter of an entire root system will decrease with increasing temperature, if root elongation and root branching increase with increasing temperature. In contrast, the root diameter of individual roots that are from the same branching order and are of equal length may have similar root diameters at both the higher and the lower temperatures.^[1]

Fig. 1 Root temperature response of maize (*Z. mays* L.) root dry weight at 24 days after germination.

Source: From Brouwer.^[2]

ROOT DEVELOPMENT

Root initiation is a developmental process that responds to soil temperature. The number of lateral roots of cotton and sunflower (*Helianthus annuus* L.) seedlings changed in response to soil temperature in a manner similar to that of root length or root dry weight.^[5] The number of lateral roots increased from zero at low temperatures to maxima at 27°C for sunflower and 35°C for cotton. Above the optimum temperature, the numbers of laterals decreased rapidly. Root initiation can also be described in terms of accumulated degree-days or thermal time for temperatures below the optimum (Fig. 3),^[1] which is normally the case in temperate regions. Accumulated degree-days are calculated by summing up over a period of days, and the difference for each day between the daily mean temperature

Fig. 2 Increase in taproot length of pecan (*Carya illinoensis*) seedlings after 4 days of growth at the treatment soil temperature.

Source: Data from Woodroof & Woodroof.^[8]

Fig. 3 The relationship between the number of lateral roots of pearl millet (*P. typhoides* S. & H.) and accumulated degree-days (base 12°C) at the shoot meristem during the period 4–22 days after planting.

Source: From Gregory.^[9]

and the minimum temperature required for root initiation. Studies of pearl millet (*Pennisetum typhoides* S. & H.), for which the minimum temperature of initiation is 12°C, have shown that the numbers of lateral roots and adventitious roots were strongly correlated to accumulated degree-days.^[9] In other words, both the length of time and the temperature during that time controlled the number of lateral and adventitious roots. Interestingly, the numbers of seminal roots of oat, wheat, and maize are not determined by soil temperature because the seminal root initials are already present in the seed embryos at the time of planting.^[1]

There have been few studies that have examined the effect of soil temperature on root maturation and turnover. In general, roots at low temperatures remain white and succulent longer than roots grown at high temperatures, which become brown and shriveled more quickly. In one study, root longevity of several grass species was observed to be greater at a site with cooler soil temperatures than at a similar site with warmer soil temperatures.^[10] Root production and standing numbers of roots, however, were greater at the warmer site. Another indication of root maturation is the suberization of endodermal cells. For maize roots of similar length, suberization occurred closer to the apex at higher

soil temperatures, indicating that low temperatures delayed root maturation.^[1]

ROOT ORIENTATION

Roots of many plant species grow out from the plant's main axis at a specific angle from the vertical rather than straight down. The angle at which these roots grow is temperature sensitive.^[1] In general, cooler temperatures tend to cause more horizontal growth, and warmer temperatures result in more downward growth. Additionally, maize and soybean (*Glycine max* [L.] Merr.) genotypes differ in the temperature response and sensitivity of the growth direction of their roots.^[1]

ROOT RESPONSE TO SOIL TEMPERATURE GRADIENTS

In temperate regions, soil temperatures below the depth of 30 cm are usually less than the optimum temperature for root growth of summer annual crops like cotton, maize, and soybean at the start of the growing season. As the growing season continues, the temperatures of the deeper soil layers continue to increase until canopy closure and decreasing air temperatures halt the process. Because warming of soil layers progresses downward from the surface, some deep soil layers may never reach the optimum temperature for root growth, and at greater depths, the soil may only warm to a few degrees above the minimum root growth temperature. As a result, the downward extension of crop roots may be limited by the cool temperatures of the subsoil layers.^[1,6] A controlled environment experiment in which temperature gradients were established in soil columns has shown that the rate of downward growth of cotton and soybean roots is limited by temperature gradients and the rate at which soil warming progresses from the surface.^[6] These results corroborate field observations of soybean rooting depth increases that seemed to follow the 17°C isotherms downward from the surface.^[1]

CONCLUSION

Root system expansion is a function of three temperature-dependent processes: growth, development, and orientation. Temperature affects root growth through its influence on root weight, root length, and root diameter. Root development is influenced by the effect of temperature on root initiation and root turnover. Finally, temperature controls root orientation through its impact on the direction of root growth.

Crop Rotation and Farming Systems: Temperate Zone

Martin R. Carter

Agriculture and Agri-Food Canada, Charlottetown, Prince Edward Island, Canada

Abstract

Crop rotation and farming systems play major roles in soil structure management, especially in temperate zones where moderate climates provide a potential for accumulation of soil organic matter and related improvements in soil structure. *Soil structure* can be defined as the spatial arrangement of both soil particles and voids, and improvements in its quality are positively related to crop and soil management practices, such as organic matter inputs (e.g., continuous cropping, organic amendments), soil nutrient management (e.g., fertilizers, calcium amendments), and conservation tillage practices. Increasing organic matter inputs through crop rotation, which enhances the supply of structure-forming agents (e.g., humic substances, plant roots, fungal hyphae, and soil fauna), is the major contributor to soil structure management in temperate soils.

SOIL STRUCTURE MANAGEMENT IN TEMPERATE AGRICULTURE

Soil structure can be described in the broadest sense as the spatial arrangement of both soil particles (aggregates) and voids (pores), which has significant effects on air–water relationships in soil.^[1–3] The shape, size, and stability of aggregates in cultivated soils can be greatly modified by crop rotation and farming practices.

Soil Structure in Temperate Zones

A useful approach to understanding the management of soil structure in temperate agriculture, which accommodates both aggregates and pores, characterizes structure on the following basis:^[4]

- Structural form—arrangement and size of the pore space
- Structural stability—ability to retain the distribution and size of aggregates after exposure to various stresses (e.g., external forces of impact, shear, abrasion, and slaking)
- Structural resiliency—ability of a soil to recover its pore-space arrangement after the removal of a specific stress (e.g., compaction)

On a macroscopic scale, soil structural form can be characterized by soil bulk density. Pore-size distribution, however, provides a more detailed measure of structural form. Pore space can be categorized on the basis of the dominant water process (i.e., water transmission or storage pores).

Although both the pore and aggregate viewpoints are useful, the latter usually dominates through ease of

measurement. It assesses soil structural stability on the basis of the stability of a certain aggregate size. The level of dispersed clay can also provide a useful index of soil structural stability, especially for processes involving reduced permeability, sodicity, and soil crusting.^[2]

Soil structural resiliency is characterized by assessing a soil's ability to self-generate structure through natural processes. Biological processes, such as the activity of soil fauna; physical processes, such as freezing–thawing and wetting–drying, are the main agents involved in structure recreation at the soil surface.^[4] These “self-mulching” soils are mainly clay to clay loams that undergo sufficient swelling to allow structure formation.

Soil Structure-Forming Agents in Crop Rotation and Farming Systems

The formation of soil aggregates is dependent upon both abiotic and biotic factors, the former being related mainly to soil clay content and the capacity for natural structure-forming processes (e.g., alternating shrink–swell, freeze–thaw, and wet–dry). In the temperate zone, organic matter (i.e., biotic factor) plays the major role in soil structure formation and management. The structure-forming process occurs with some degree of order.^[2,4] This ordering or arrangement of particles and aggregates can be viewed conceptually as a hierarchy consisting of three main orders:^[2] clay microstructures (<2 μm diameter), microaggregates (2–250 μm diameter), and macroaggregates (>250 μm diameter).

In clay microstructures, clay–organic matter complexes are stabilized by humic acids and inorganic ions [e.g., calcium (Ca)]. Microaggregates are stabilized directly by microbial materials, such as polysaccharides,

hyphal fragments, and bacterial cells or colonies.^[2,5] In comparison, the formation of macroaggregates and their temporary stabilization is the result of a combination of mechanisms related to plant roots and the activity of soil fungi and fauna^[5] (Table 1). Soil fauna, strongly associated with structure formation, is a major determinant of soil processes influencing nutrient cycling, aggregate formation, and permeability of soil.^[6] Macrofauna (e.g., earthworms) influence the formation of large soil pores and play an important role in preferential flow.

Importance of Soil Structural Quality in Temperate Farming Systems

Management of soil structure is needed to ensure the maintenance of soil structural quality, which is important for many soil functions, including serving as a medium for root growth and development and regulation of water and air.^[1] Inherent soil properties, such as clay content, influence the magnitude of the soil water-holding capacity. This is also augmented by the organic matter content. Dynamic soil structural properties, such as soil density and porosity, control the soil storage capacity for water and air. Pore size distribution, considered a good indicator of the soil structural condition, has proven useful in predicting water infiltration rates, water availability to plants, soil water storage capacity, and soil aeration status. Macroporosity, air permeability, and/or oxygen diffusion rate provide a measure of soil macropore continuity and organization. Soil strength and aggregate stability reflect a soil's ability to resist compaction and other stresses that can lead to loss of structure.

Table 1 Benefit of crop rotation on soil structure in temperate soils: agents, processes, and scale of structure formation.

Structure-forming agent	Structure-forming process	Scale of structure
Humic substances; hydroxides of iron and aluminum; polyvalent metal cations (e.g., Ca); clays	Allow bonding between soil mineral and organic components	Microaggregation
Polysaccharides	Gelatinous glue; organomineral bonding	Micro- and macroaggregation
Plant roots; fungal hyphae	Enmesh soil aggregates; exude polysaccharides	Macroaggregation
Soil fauna (e.g., earthworms)	Mix organic matter with soil colloids; form large pore or gallery networks	Macroaggregation

Source: From Carter & Stewart.^[2]

BENEFITS OF CROP ROTATION ON SOIL STRUCTURE

In the temperate zone, soil structure and organic matter accumulation are interrelated: organic matter (or fractions thereof) is basic to the structure-forming process, while organic matter sequestered within microaggregates is protected against decomposition. However, crop rotation, land use and farming system, and soil and crop management practices influence the degree of soil structure.

Perennial Forages and Pastures

Water-stable macroaggregation increases rapidly when perennial forages and grasses are utilized in crop rotations. Maximum stability is often achieved after 3 to 5 years.^[7,8] Grass roots and fungal hyphae are the main aggregating agents involved in forming and stabilizing macroaggregates.^[9] Early improvement in water-stable aggregates is related to soluble carbohydrates and microbial biomass.^[2] Choice of perennial forage crop species and cultivar can also influence the extent of aggregate formation and stabilization.

Short-Term Rotations and Cover Crops

Crop rotation, an ordered sequence of crops on the same land, and the use of cover crops mainly in row crop systems [i.e., maize (*Zea mays* Linnaeus) and potato (*Solanum tuberosum* L.)] provide important benefits to soil structure in temperate agriculture. The degree of structure modification, especially improvement of water-stable aggregation, is dependent on crop species and, in particular, the amount of residue that each crop of the rotation returns to the soil. Carbon inputs vary widely among crop species. Generally, an annual input of 2–3 Mg C ha⁻¹ is required in temperate soils to prevent a decline in soil organic matter concentration and soil structure.^[2]

Organic Additions, Fertilization, and Ca

Many organic materials are applied to agricultural soils, such as manure, compost, and sewage sludge. The most widespread is farmyard manure. Organic additions and inputs can lead to the formation of water-stable macroaggregates.^[2,10] However, organic materials vary widely in composition and, consequently, differ in their rate of decomposition and resultant benefit on soil structure and organic matter content.

Mineral fertilizer, nitrogen in particular, can have both positive and negative effects on soil structure and organic matter. The potential improvement in soil aggregation associated with increased production of roots due to fertilization may not be fully realized if fertilization also causes increased rates of mineralization of the binding agents.^[4]

Common Ca amendments (e.g., lime, gypsum) can lead to soil structure formation and stabilization. The Ca functions as an agent that promotes bridging of microbial cells and clay minerals to form organomineral microstructures.^[2]

Soil Cultivation and Conservation Tillage

Long-term studies have shown that cultivation of native soils has resulted in a loss of soil organic carbon and a subsequent decline in soil structure.^[11] Some of this loss would be associated with a change in vegetation or cropping (e.g., from native grassland to annual grains) and the resulting decrease in organic matter inputs to the soil. Reducing the amount and degree of tillage intensity and retaining a soil cover of crop residues (i.e., conservation tillage; >30% soil residue cover) can lead to an accumulation of organic matter in the surface layer (5–10 cm). This increase in organic matter yields major benefits for improved soil structural stability and soil physical quality.^[2,5] However, in comparison, the mixing effect of tillage increases the association of mineral and organic particles, resulting in the beneficial formation of organomineral microstructures.^[12] Although in many cropping practices (especially conservation tillage), the mixing activity of soil macrofauna may complement, to some degree, the role of tillage.^[6]

Crop Rotation and Farming Systems: Tropical Smallholder Farm Systems

Stefan Hauser

Agronomy, International Institute of Tropical Agriculture, Ibadan, Nigeria

Lindsey Norgrove

Department of Environmental Sciences, University of Basel, Basel, Switzerland

Tarcisius Nyobe

Institute of Agricultural Research for Development, Nkolbisson, Cameroon

Abstract

Typically tropical smallholder farm systems are characterized by the use of fire as a clearance tool, the incorporation of a fallow phase, the lack of mechanization and external purchased inputs, and a high reliance of manual labor. While land husbandry practices are therefore relatively benign, farmers can be forced to cultivate marginal land, such as steep slopes, which might increase the risk of soil structural degradation. We outline the role of fallow and land husbandry techniques in determining soil structure. We then outline methods used by smallholder farmers that can minimize soil structural degradation. We then give examples of local methods used by smallholder farmers to rehabilitate structurally degraded or marginal soils to permit cultivation.

INTRODUCTION

Soil structure is the manner in which soil mineral particles and organic matter are spatially arranged into groups or aggregates and the arrangement of voids between the solid materials. It depends upon soil texture, clay type, the quality and quantity of soil organic matter inputs, and the activity of soil biota (e.g., microflora, plant roots, and soil fauna). Soil structure is characterized by porosity, pore size distribution, and pore continuity. These can be assessed by measurements of penetrometer resistance, soil bulk density, water infiltration rate, hydraulic conductivity, and soil aggregate stability.

SMALLHOLDER AGRICULTURE AND THE IMPORTANCE OF SOIL STRUCTURE

Most smallholders in the tropics practice shifting cultivation or other forms of “slash and burn” agriculture, so these are the focus of this entry. Slash and burn agriculture is a generic term for agricultural systems in which the fallow vegetation is manually slashed, left to dry, and cleared from the field by burning before crop cultivation.^[1] After a cropping phase, the land is abandoned to a fallow phase. Later, the cycle is repeated.

Relative to undisturbed forest or fallow land, generally, soil structure is degraded through clearance to agriculture. In South America, compared with undisturbed forest, continuous sugar cane production for 20 years on both Oxisols

and Alfisols resulted in reductions in wet aggregate stability at low water contents, threefold reductions in pore tortuosity, and thus higher unsaturated hydraulic conductivity. In the Oxisol, total porosity was reduced under cultivation, but in the Alfisol, land use change had no significant effect.^[2] Other studies in the region on Ultisols^[3] and Oxisols^[4] have found higher soil bulk density^[3,4] and low soil moisture content^[3] after slash and burn, compared to undisturbed forest. In West Africa, clearance and burning resulted in decreases in soil macroporosity and infiltration rates after both short and long fallows.^[5] In a drier environment in Southern Africa, clearance of miombo woodland to cropland generally decreased soil aggregate stability and resulted in reduced soil infiltration rates on clay but not on sandy soils.^[6]

However, such structural changes may not be the limiting factors in crop production. Many soils in the humid tropics are constrained by low nutrient reserves rather than by soil physical properties. For example, there were few differences in soil physical properties between “productive” and “non-productive” land as classified by smallholder farmers in central Kenya, although there were substantial differences in soil chemical properties.^[7] In most tropical soils, most nutrients are concentrated in the shallow topsoil, subtended by the nutrient-poor and acid subsoil. Thus, the retention of the topsoil is of paramount importance for sustained crop production. Land use practices that cause structural collapse reduce the topsoil’s ability to absorb and conduct water. On sloping land, this leads to surface runoff and soil erosion, which can completely

remove the topsoil layer, exposing infertile subsoil unsuitable for agriculture and unlikely to be reclaimed by vegetation.

The Importance of Fallow

Slash and burn smallholder systems can be subdivided according to the fallow length employed and the climatic zone in which they are practiced. The basis of the processes leading to soil aggregation during fallow phases is biomass production as an energy supply. Litterfall and root turnover apply and incorporate biomass into the soil. Therefore, generally soil organic matter levels increase with time under fallow.^[8] The fallow vegetation covers the land, preventing particle detachment by wind and rain. Shade and the increased soil organic matter levels encourage macrofaunal activity.^[9] Mites, collembola, earthworms, termites, and ants burrow in the soil generating macropores connected to the soil surface. These pores provide for rapid water infiltration during intensive rainstorms.^[10]

The Importance of Fallow Length

In some areas of the humid tropics, farmers clear primary or secondary forest and return to the same land after a forest fallow phase of 10–30 years. These systems are perceived to be sustainable as fallow recovery is complete.^[1] Indeed, in West and Central Africa, farmers most frequently rank fallow age first of the criteria they use to determine which parcel to recultivate.^[11] However, many smallholder farmers face a shortage of land, so fields are cleared after shorter, suboptimal fallow periods,^[12] with insufficient regeneration.

The Impact of Climatic Zone

With decreasing rainfall, the climax vegetation shifts from forest to savanna, shrubland, and grassland. A minimum amount of time is required to reestablish the climax vegetation after clearing and cropping. In areas with low rainfall, biomass production is limited. Soil protection relies on other, mainly physical measures preventing or reducing soil exposure to forces degrading soil structure. Windbreaks, stone bunds, ridges, and mulching are measures used by farmers to reduce wind erosion, some of them indirectly through water harvesting and retention.

HOW SMALLHOLDER FARMERS CAN INFLUENCE SOIL STRUCTURE

Smallholders can modify soil structure only through the promotion of soil aggregating factors and processes increasing soil porosity. These factors are largely biological processes, e.g., plant root growth, aboveground and belowground plant biomass decomposition, the breakdown of

organic matter by soil microbes, forming humic substances, and soil mesofauna and macrofauna, such as collembola, mites, termites,^[13] and earthworms,^[14] which ingest and mix mineral soil particles and organic matter. The selection of the land, clearing method employed, whether the land is burned or mulched and tilled or not, the use of inputs, and the management of fallow are the smallholder's tools to balance soil structural degradation vs. structural regeneration.

Site Selection: Avoiding Slopes and Soil with Low Structural Resilience

Slash and burn farmers have topographic preferences. In Southern Cameroon, on structurally unstable Ultisols, farmers prefer the plateaux and avoid cropping even on gentle slopes.^[1] However, farmers' choices are increasingly limited by the type of land available, so unsuitable land is taken into crop production, increasing the risk of degradation.

Clearing Method

Smallholder farmers generally clear bush or forest manually, using machetes and, in some cases, chainsaws. Compaction, which would occur with mechanized clearing by bulldozer, is avoided. For example, in the Amazon basin, the effects of mechanical and manual clearance were compared.^[15] Prior to clearance, infiltration rates were 420 mm h⁻¹. Manual clearance reduced infiltration rates to 304 mm h⁻¹, whereas mechanical clearing reduced infiltration rates to 32 mm h⁻¹. All clearing methods increased topsoil bulk density to 15 cm depth; however, only mechanical clearing caused significant increases to 25 cm depth. There was no effect upon soil texture. Similar results were obtained in analogous experiments on an Ultisol in Southern Nigeria.^[16]

In the humid forest zone, farmers traditionally retain certain trees in their fields. In Southern Cameroon, persistent pioneers such as *Ceiba pentandra*, *Triplochiton scleroxylon*, and *Terminalia superba* are most often retained to create a level of shade deemed appropriate for some of the more shade-tolerant food crops cultivated, such as plantain. Farmers also consider that such trees maintain soil fertility through leaf litterfall and subsequent decomposition.^[17] Retention of living trees, as compared to clear-felling them, was shown to maintain lower soil bulk density and higher infiltration rates on a Southern Cameroonian Ultisol.^[18]

Burning vs. Mulching

In burning experiments conducted in Southern Cameroon, burning had no effect on bulk density and penetrometer resistance.^[1] It has been reported in the literature that the burn loosens the soil and facilitates tillage and planting. Direct measurements in Southern Cameroon could not confirm these reports, and the reports might refer to the lack of litter and shallow root biomass, rather than any changes in the soil. Where hot burns are attained, such as under a log,

compaction and soil structural collapse can occur due to a relative excess of monovalent cations, leading to a breakdown of cation bridges between clay minerals, the combustion of soil organic carbon and thus substances binding soil particles, and the elimination of soil macrofauna and microfauna mixing soil particles and organic materials to form stable aggregates.

After land clearing and burning, the soil surface is exposed to the impact of raindrops. The retention of biomass would reduce the impact of raindrops and through decomposition would contribute to soil structural maintenance. Mulch layers prevent detachment of soil particles and are conducive for soil biota such as earthworms, which produce stable soil aggregates by casting.

In semiarid zones, where mulch is applied to crusted soil, termite activity can be triggered, and this can have positive effects upon soil structure. In Burkina Faso, in plots mulched with a wood–straw mixture, saturated soil hydraulic conductivity was $3.6 \times 10^{-5} \text{ m s}^{-1}$ when termites were present and was $0.34 \times 10^{-5} \text{ m s}^{-1}$ when termites were excluded.^[19]

However, mulching is not a generally applicable solution, because not all crops respond well to a mulch layer and require a “clean” soil surface, and there is also incompatibility between the use of tillage and *in situ* mulch.^[20] However, for other crops, such as plantain, mulching can be universally recommended.^[21] In systems without fallow phases, mulch has to be produced during cropping phases by a cover crop or intercropped tree or shrub hedgerows (see the section “Improved Planted Fallows”).

Tillage vs. No Tillage

Farmers have various reasons for tillage, depending on site conditions and the intended crop. Tillage can loosen crusted and compacted soil, increase the depth of the loose soil layer, mix ash and residue into the soil to avoid nutrient losses by runoff, and concentrate topsoil through mounding. Breaking-up of soil aggregates increases the decomposition rate of soil organic matter, previously physically protected, and thus contributes to increased nutrient availability. Accordingly, the purposes of tillage range from water harvesting to nutrient supply and accumulation in small areas. It can generally be assumed that tillage does not contribute to soil aggregation. Its loosening effect is temporary, and rain may disintegrate soil aggregates further, leading to more severe crusting and compaction. Some crops, however, do require tillage, and this exposes the soil and can lead to structural degradation.

Under humid conditions, tillage is mainly serving the requirements of certain crops. Groundnut (*Arachis hypogaea*), for instance, requires its pegs (fertilized ovules) to penetrate the soil. To form grains, the crop has to take up Ca^{2+} through the pod walls. Therefore, the soil is tilled with hand hoes, mixing Ca^{2+} -rich ash with the soil at seeding. Other crops may require a deeper layer of loose soil than is

available. This requirement is achieved by mounding for crops such as yam (*Dioscorea spp.*), which form a tuber that grows with a blunt end vertically into the soil. Any obstacle will stop tuber growth and lead to deformed, unmarketable tubers. Other crops planted in smaller mounds are sweet potatoes (*Ipomoea batatas*) and tannia (*Xanthosoma sagittifolium*), which may not require a deeper layer of loose soil but may positively respond to an increased amount of nutrients. Furthermore, tubers are more easily harvested from mounds than flat soil, especially during dry seasons, when soils are hard.

A study summarizing more than 20 years of research in semiarid Southern Africa on tillage in maize systems assessed the impact of “traditional” animal draught tillage versus manual “conservation” tillage in maize concluded that its impact was dependent on the general yield level of the farm and the rainfall in the area.^[22] At low yields (less than 2.5 Mg ha^{-1}) and low rainfall (less than 500 mm yr^{-1}), conservation tillage conferred a yield advantage. Above these levels, conventional tillage was advantageous, although results were variable. In the forest–savanna transition zone of central Cameroon, tractor tillage in tomato systems resulted in significant reductions in aggregate stability, lower aggregate mean size, and higher meso-aggregate proportions, compared with manual tillage and no tillage. The effects of the last two techniques could not be distinguished.^[23]

Manuring, Compost, and Fertilizer Application

Although primarily used to apply nutrients, the high organic matter content in manures and composts has positive effects on soil aggregation. This is mainly caused by the processes of decomposition and ingestion and egestion by soil mesofauna and macrofauna. In drier areas, manure is usually incorporated by tillage (see the section “Tillage”) to facilitate biological activity which would be hampered at the surface due to drought. The major constraints are the low quantities of manure and compost available and the high labor requirement for transport and incorporation. Organic matter inputs will increase if crop biomass production increases. For most crops, only a proportion of the plant is harvested and various amounts of biomass will remain in the field (unless required for livestock feeding). Judicious fertilizer use can increase biomass production, crop yields, and thus the amount of organic matter returned to the soil. Furthermore, a fertilized crop may grow more vigorously and cover the soil earlier and, more intensively, reduce the negative impact of rain.

Improved Planted Fallows

If shortened natural regrowth fallow is not capable of restoring soil properties to a level at which adverse effects on long-term suitability of the soil for crop production can be avoided, planted fallows may be an alternative. There

are two main types of planted fallow: herbaceous legume fallow and tree-based or shrub-based fallow. In southwestern Nigeria, under *Pueraria phaseoloides* live mulch and *Leucaena leucocephala* alley cropping, aggregate stability, measured as mean weight diameter (MWD), was higher than in natural regrowth system when both were continuously cropped.^[24] The differences between the fallow types diminished with increasing fallow length. MWD variation over time was less under *P. phaseoloides* live mulch. On a Southern Cameroonian Ultisol, increased infiltration rates, reduced soil temperature, and reduced penetrometer resistance occurred in a tilled alley cropping system using *Senna spectabilis* compared with a tilled, no-tree control.^[25] However, planted fallows do not always have more positive effects on soil physical properties than on the natural regrowth.^[24]

EXAMPLES OF INDIGENOUS SYSTEMS OF SOIL STRUCTURAL MANAGEMENT

Traditional smallholder management techniques can be divided into those that, whether inadvertently or directly, aim to maintain soil structure and avoid degradation and those that are used in already-degraded environments or on marginal soils to try to aid soil rehabilitation. From a systems perspective, changes in smallholder systems are probably non-linear and prone to hysteresis effects,^[26] and thus, small changes in management might provoke a cascade of effects resulting in a downward degradative spiral. Once a system is degraded, huge efforts might be required to return to achieve the previous state. Many of the techniques in the former category, such as maintaining trees in fields, mulching, and using planted fallows, have been dealt with in the previous sections. Some of those in the latter category will be described below.

In the Sahel, smallholder cereal farmers use a traditional technique of pits referred to as *Zai* in Burkina Faso, *Tassa* in Niger and *Towalen* in Mali.^[27] This is used on soils, known as *zipellé* in Burkina Faso, which have lost their structure and have become sealed and crusted. Farmers dig small holes of 15–30 cm diameter and about 10–20 cm deep. During the dry season, fine sand and litter are trapped in these holes. Farmers apply animal manure and plant residues, attracting termites. The termites build stable channels in the soil under the manure to access it and distribute some of the organic material. Once the rains commence, the holes collect water, rapidly conducted in the termite channels, thus avoiding runoff. The fine sand can retain more water than coarse sand, while the organic layer reduces evaporation, thus reducing the risk of seeds failing to germinate. Sorghum, millet, and cowpea are commonly planted in the *Zai*.^[28] Crop yields can be more than tenfold higher than in no *Zai* controls, and the holes can be reused for 3 years.^[29] Exclusion experiments have demonstrated the critical role of termites in the system as their activity

increased hydraulic conductivity and soil porosity, and these differences were amplified when additional mulch was added to further stimulate termite activity.^[19]

In Tanzania, similar pits called “Ngoro” have been traditionally used for hundreds of years by the Matengo people in southern Tanzania to permit cultivation of Oxisols and Ultisols on steep slopes.^[30] The pits are larger than those used in the Sahel and are traditionally 1.5 m × 1.5 m square by down to 0.5 m deep, although sizes are variable. Plant residues such as cut grasses are buried under the pits, and maize is cultivated on the ridges of the pit where the soil from the pit is piled. Although runoff and erosion occur, the losses are small because most of the soil is deposited in the pits. Ngoro production systems have been documented to effectively conserve water, soil, and nutrients on sloping land.^[30]

Abstract

Cropping swelling soils in the tropics and subtropics is a challenge of managing climate variability and developing systems that can respond to this variability. Fixed rotations may not suit this combination of soil and climate. As water supplier is a commonly limiting factor in sustainable crop production, optimizing water storage and use is a central theme of good systems. Optimizing water entry is achieved by retaining a surface cover on the soil, especially when high energy rainfall is expected. Systems that are responsive to water availability make the best use of rainfall and minimize off-site impacts of erosion. Inclusion of a pasture phase in rotations can be important in maintaining soil organic carbon and structure.

INTRODUCTION

Large areas of swelling clay soils (Vertisols) occur in arid and semiarid tropical and subtropical regions of Africa, India, and Australia and are increasingly being relied on to produce food for the growing population. Farmers of Vertisols are often dealing with poor resources and face many risks and constraints associated with soil and weather interactions. These regions usually have wet and dry seasons, but rainfall may be highly variable between years and within seasons. Intense rains may follow long dry periods. In some areas, a high proportion of annual rainfall may be in light falls that do not wet below the surface and are quickly lost by evaporation. In other areas, there may be long wet periods in which waterlogging and weed growth present major problems for farmers.

Vertisols have long been recognized as difficult to farm, because they are soft and sticky when wet and hard, and intractable when dry. The swelling characteristics arise from the high proportion of montmorillonite clays. Forces associated with the interaction between water and the highly active clay particles are extremely powerful and usually predetermine soil structural relations in the soils. Management inputs will have the best effect if they work in

harmony with these forces. For example, the aggregation characteristics strongly influence the effects of tillage and the nature of pore spaces available for roots and water entry.

Cropping Vertisols alter water and carbon balances. For example, changes in soil cover and hydrology as a result of cultivation can result in doubling of annual runoff and increasing soil erosion by a factor of 100.^[1] Also, tillage reduces organic matter in the soil surface,^[2] while the use of large tractors compacts subsurface soil.^[3] Fallowing is a key management tactic in rain-fed farming. A distinguishing feature of Vertisols is their very high infiltration capacity when dry and cracked, in contrast to low infiltration rates when wet.^[3] Low infiltration rates are generally a result of a crusted or saturated surface, a wet profile,^[4] or a poor internal drainage due to compaction or loss of structural voids. High erosion rates associated with bare soil fallows are clearly unsustainable, far exceeding likely soil formation rates.^[1] Loss of productivity associated with shallow soils and nutrient depletion results in lower biomass production and declines in organic stores in soil. While all soils are vulnerable to compaction, the ability of clay soils to store water for long periods makes them particularly susceptible, with subsoils being above the plastic limit for much of the time.^[5] The hidden nature of

subsoil compaction and variable crop responses make the diagnosis and quantification of impacts of compaction difficult.

OPTIONS FOR MANAGING SOIL STRUCTURE

Retaining Soil Cover

Soil cover (from growing crops and their residues) and reduced tillage maintain infiltration by reducing aggregate disruption by raindrops.^[6,7] The amount of crop residue available to provide surface cover is determined by crop type, yield, and tillage method.^[8] Reduced tillage and no-till practices result in less stubble breakdown and minimize the deleterious features of tillage while maximizing water storage.

Maintenance of soil cover can reduce erosion rates by an order of magnitude,^[1] thus protecting the soil resource base. Tillage systems with high nutrition levels and crop residue retention can also maintain higher organic carbon levels.^[9]

Rotations to Manage Soil Moisture Deficit

Soil moisture content is the most important factor in determining infiltration into cracking clay soils. Although seasonal conditions have a strong and uncontrollable influence on soil moisture, the sequence and number of crops grown have a major effect on the timing of soil water deficits during the year and hence on runoff.^[10] Rotations that grow more crops, or crops grown during the wetter season, have lower runoff and deep drainage. One element of a system to improve water use efficiency includes planting of crops before the onset of the wet season to make better use of incident rainfall.^[11] Increasing cropping intensity can also result in greater total productivity although the yields per crop may be reduced.^[12] The concept of “opportunity” or “response” cropping involves matching cropping intensity with rainfall expectancy and moisture conditions. Crop rotations are based more on existing conditions rather than on a fixed pattern, thus exploiting above average rainfall conditions when they occur. Rotations that maintain a higher soil water deficit are also less prone to compaction damage due to being below the plastic limit for a greater proportion of the time.

Exploiting Soil Cracking

The cracking nature of Vertisols offers potential to capture intense falls of rain that might otherwise be lost as runoff. Rapid water movement to depth via cracks can occur during high intensity rainfall and provides a means for improving the efficiency of water storage. Tillage should be avoided as it may close cracks that

would otherwise channel water below the highly evaporative surface soil.

Tillage and Roughness

Tillage, although superimposed on structural arrangements produced by wetting and drying, influences aggregate and pore size distribution, roughness, residue cover, and strength of the surface soil.^[13] Tillage can increase infiltration by breaking surface crusts and by increasing surface porosity and surface storage capacity.^[14] In some situations, smooth soil surfaces associated with no-till systems can result in higher runoff compared to tilled soil.^[6] Depression storage can be created using specialized tillage equipment. Its function is to store excess rainfall, allowing greater time for infiltration. Such storage is variously referred to as furrow dikes, tied ridges, or pits. A particular example of surface configuration used to improve productivity and reduce risk is the broad bed and furrow system developed to allow double-cropping on Vertisols at the International Crops Research Institute for the Semi-Arid Tropics.^[14] This system reduces the risk of waterlogging and, by controlling runoff, reduces soil erosion.^[15]

Deep tillage (20–40 cm depth) has been practiced to reduce runoff, an improved water storage and root growth, but results have been variable. Deep ripping (35 cm) prior to wheat and sorghum on a poorly structured clay in southern Queensland has only short-term benefits, not sufficient to justify the cost.^[16] In contrast, deep tillage reduced runoff and erosion on a steep (14%) cracking soil in Southern Italy.^[17] The variability in results between studies suggests caution in applying deep tillage.

Zonal Wheel Traffic to Reduce Compaction

The possibilities of conserving energy and time associated with confining wheel traffic to permanent laneways are being explored to determine whether there were improvements in soil physical conditions through removal of tractor wheel loads and compaction.^[18] The system involves creating permanent tracks for most machinery operations to follow. Global positioning system technology is being employed to guide machinery operations. Advantages of this “controlled traffic” system are as follows: less overlap of implements leading to greater efficiency, lower draft requirements,^[3] more timely planting and spray operations, and less compaction of the majority of the crop-growing soil mass. A trafficked micro-catchment yielded considerably more runoff (30–60 mm) compared to an untrafficked area.^[19] The energy implications of controlled traffic also make the system attractive by improving the efficiency in the application of seed and chemicals. Soil benefits are not always expressed as improvements in yield^[19] although consistent yield advantages have been observed on a clay loam.^[20]

Pasture Phases to Rebuild Organic Carbon and Structure

Soil organic matter declines with cultivation, with associated loss of nutrient supply capacity and soil structure.^[2] Incorporating a pasture ley in a cropping system has the capacity to increase soil organic matter and improve infiltration characteristics.^[21,22] The use of pasture leys in Mediterranean cropping systems is well established but is not common in clay soils in the subtropics.

With many interactions between soil, weather, and crops in cropping systems, the design of improved cropping systems is difficult to explore when based wholly on experimentation. Results from a sequence of seasons may not be representative, and options are restricted by logistics. Cropping system models can be valuable tools in the exploration of new options for improving both the economic and natural resource sustainability of alternative rotations and management systems. As an example, the APSIM-SWIM model^[23,24] was used to explore interactions between changes in soil properties resulting from rotations of crops and pastures, providing predictions of variables such as soil organic carbon and wheat crop yield.^[25] Such models allow extrapolation of experimental results beyond the experience and locations where detailed experiments have been conducted. In general, cropping systems that have high fertilizer inputs and less tillage result in improvements in soil organic matter, infiltration characteristics, and yield. Analysis of time series of costs and returns then allows for a robust analysis of economic performance.

CONCLUSION

Soil structure in swelling soils is closely related to soil-weather-plant interactions. These interactions need to be taken into consideration when designing improved soil-crop strategies. The manipulation of soil cover and moisture content can be used to improve infiltration and moisture conservation, leading to better production and reduced soil erosion. Tillage systems that reduce soil compaction improve both production efficiency and soil function. With the incorporation of pasture leys in cropping systems, an improvement in the organic carbon status can be achieved. Relatively slow soil responses to pasture phases make such management options economically difficult for many land managers. System models provide a means to explore some of the biophysical interactions in cropping-tillage systems. When used in conjunction with field experimentation, new management systems can be efficiently developed.

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Soil compaction is a global problem and is a severe factor in crop production. This entry describes the consequences of soil compaction on crop yields, and discusses methods and strategies of alleviating and minimizing risks of soil compaction. Soil compaction is the process of rearrangement of soil particles, leading to decrease in total pore space and pore size, and increase in bulk density. It is expressed in terms of dry bulk density, porosity, hydraulic conductivity, soil strength, infiltration rate, and crop yield. It may be tillage-induced or traffic-induced. Compaction in the plow layer is largely related to the contact pressure of the tires, and that in the subsoil to the axle load. Compaction affects soil properties and processes, and influences long-term soil productivity as well as resource economy and environmental quality. Effects of compaction on plant growth and yield depend on soil, crop, and climatic conditions. The crop response to the traffic varied between sites and years, and there was a persistent negative crop response to high axle-load traffic. Compaction increases soil strength that adversely affects root growth and reduces crop yields. Use of large and heavy farm equipment increases risks of reduction in crop yields by 5–75% due to soil compaction. Strategies of managing compaction include soil and tillage management. This can be accomplished through the use of no till, controlled traffic system, crop rotations, mulching, incorporation of deep-rooted leguminous crops in rotation, and periodic chiseling. Alleviation of soil compaction can increase yields by 20–70%.

INTRODUCTION

Soil compaction or densification is the process of rearrangement of soil particles, leading to decrease in total pore space and pore size, and increase in bulk density. A large portion of soil air is forced out of the root zone, and the channels of greatest continuity and least resistance to air and water movement and root penetration are eliminated. Compaction below the depth of normal tillage operation is generally called subsoil compaction. Soil compaction may be tillage induced or traffic induced. The tillage-induced compaction, caused by primary tillage under less than optimum soil moisture conditions and by excessive secondary tillage, leads to densification of the plow layer. The traffic-induced compaction, caused by wheel traffic associated with farm operations, occurs in the subsoil. Compaction in the plow layer is largely related to the contact pressure of the tires, and that in the subsoil to the axle load. Subsoil compaction is not easily alleviated by self-correcting processes (i.e., freezing–thawing and wetting–drying cycles). The depth of subsoil compaction depends upon vehicle weight, axle load, and wheel arrangement or ground contact pressure. Compaction can exist for hundreds of years even when there is annual soil freezing and thawing. Soil compaction is expressed in terms of dry bulk density, relative bulk density, porosity, air permeability, hydraulic

conductivity, soil strength, cone resistance, plant height, infiltration rate, water retention, and crop yield.

Soil compaction is a global problem and is a severe factor in crop production. Most research on machinery-induced compaction has been carried out in humid and temperate regions. However, it is a problem everywhere and needs to be studied worldwide, as its evaluation requires local experimental data. In developed countries, this concern about soil compaction, both in the plow layer and in the subsoil, is closely related to the adverse effects on soil structure by the use of large and heavy farm equipment, increased specialization in crop production, increased traffic and tillage necessary for application and incorporation of fertilizers and other chemicals, and early seedbed preparation and planting of many crops when soils are often wet and susceptible to compaction. However, soil compaction problems in the tropics arise from the use of heavy machinery in the land clearing and in the subsequent crop production. Adverse impacts of densification on crop yields are further accentuated by intense tropical rains, the presence of naturally occurring compacted layers, and the widespread occurrence of soil horizons with large percentage of gravel and plinthite. Soil compaction and their consequences on crop production have not been much researched in tropics as in the temperate region. The magnitude of soil compaction depends on soil type, moisture content, type of

running gear, and tyre-inflation pressure. The objective of this entry is to describe consequences of soil compaction on crop yields, and discuss methods and strategies of alleviating and minimizing risks of soil compaction.

CONSEQUENCES OF SOIL COMPACTION

Soil compaction affects chemical, physical, and biological properties and processes, and influences long-term soil productivity as well as resource economy and environmental quality.^[1] Economic impact of soil compaction may be difficult to quantify because of the confounding effects of other interacting factors, e.g., antecedent soil conditions, soil management, cropping systems, weather conditions, and seasonality.^[2] Economic effects of soil compaction may be direct due to reduction in crop yield or indirect due to less effective use of resources or inputs.^[3,4] Environmental impacts of soil compaction are related to its effects on accelerated soil erosion, transport of sediments and sediment-borne agrochemicals, and possible emission of radioactively active gases into the atmosphere. Compaction-induced anaerobiosis may accentuate emission of methane, nitrous oxide, and nitrogen oxide gases from soil.^[5] Losses of nitrogen due to nitrification are usually more on compacted than uncompacted soils.

CROP RESPONSE TO SOIL COMPACTION

Soil compactability and its effects on crop growth depend on texture, cation exchange capacity, pH, soil organic matter content, weather conditions, and crop characteristics. A series of experiments conducted by a Working Group of International Soil Tillage Research Organization (ISTRO) showed that crop response to the traffic varied considerably between sites and years, and there was a persistent negative crop response to high axle-load traffic.^[6–11] Several experiments conducted in North America and Europe also showed yield reduction up to 50%.^[12] Under extreme conditions of subsoil compaction, yield reductions of maize were up to 70%^[13] (Table 1) and adverse effects persisted for several years.^[4,10] However, in some soils, the compaction effects on yield may be none or even positive.^[21,22] The effect of different axle loads on yields of silage maize in sandy soils at four locations in the Netherlands showed that heavy axle loads reduced yields by up to 38%.^[15] In Morocco, Oussible, Crookston, and Larson^[14] found that compacting a clay loam soil to a density of 1.52 Mg m⁻³ below 0.10 m depth reduced grain and straw yields of wheat by 12–23% and 9–20%, respectively. For a loam soil in Norway, Riley^[8] observed that grain yield of barley decreased from 5.7 Mg ha⁻¹ for uncompacted control to 5.2 Mg ha⁻¹ with four passes of 26 Mg axle load, and adverse effects persisted for 2–3 years.

Soil compaction can adversely impact the establishment, growth, and yields of crops in the tropics^[23] (Table 2). An intensive mechanized cultivation of wheat in large-scale

irrigation projects can lead to the development of a dense tillage pan at about 0.15–0.20 m depths. The pan restricts root penetration resulting in reduced grain yields.^[31–33] Experiments conducted in Punjab, Pakistan^[27,28,34,35] showed that compacting a sandy clay loam soil to a density of 1.93 Mg m⁻³ below 0.15 m depth reduced grain yield of wheat by 12–38% and of sorghum fodder by 14–22%.

Ishaq^[36] reported that subsoil compaction effects persisted for 3–4 years and decreased yields of wheat by 12–18% and cotton by 7%.

MANAGEMENT OF SOIL COMPACTION

Minimizing Soil Compaction Hazards

One of the most direct methods for avoiding compaction is to adopt the strategy of controlled traffic. A controlled traffic system restricts wheel traffic to specific lanes. As a result, most of the soil area remains uncompacted compared to the uncontrolled traffic pattern. Other possible ways to manage soil strength are the use of no till, alley cropping, crop rotation or addition of manure or other organic materials, and promotion of earthworm activity.^[37]

Amelioration of Compacted Soils

Mechanical and/or biological measures can be used for alleviating soil compaction.

Mechanical loosening of compacted soil

Mechanical loosening of soil is necessary to alleviate soil compaction. The negative effects of compaction on soil

productivity require decades for amelioration.^[1–3] A study conducted in Australia by Hamza and Anderson^[38] showed that deep ripping to 30 cm depth in combination with tine spacing of 30 cm resulted in increased stored soil water and infiltration rates, decreased soil bulk density and soil strength, and increased grain yields of wheat and barley on both sandy and clayey soils. On the other hand, in Denmark, Olesen and Munkholm^[39] reported that subsoil loosening in crop rotation for organic farming eliminated plough pan with mixed effects on the yields of wheat. In Orange Free State, South Africa, Bennie and Botha^[40] reported that deep ripping of a continuously plowed soil increased maize and wheat yields. The beneficial effects of mechanical loosening are often short lived, and soils may resettle to a high density due to subsequent excessive traffic and other management.^[41] Periodic chiseling to a depth of about 50 cm in the row zone followed by sowing of a deep-rooted leguminous cover can avoid resetting of the loosened soil and improve infiltration and root development in the subsoil.^[37,42] Subsoiling in the row zone can be effective to alleviate the effect of dense layer (Table 3).^[49,56–59]

Biological loosening of compacted soil

Soil compaction can be alleviated by growing deep-rooted annuals such as mucuna or pigeon^[60] pea, or deep-rooted

Nigeria	Leguminous crops (<i>Acacia leptocarpa</i>) (<i>Acacia auriculiformis</i>) (<i>Senna siamea</i>)	Ameliorated soil compaction and soil strength	[71]
		Decreased soil bulk density	

perennials such as *Leucaenaleucocephala* (Table 4).^[61,62] Improvement in soil physical properties by legume covers is attributed to increase in the transmission or micropores (>5 µm), created by the taproot systems of legumes.^[60,63] Roots of alfalfa, sweet clover, and guar can penetrate hard pans, but improvement in yield is not clear.^[72] The roots of bahia grass can penetrate soil layers, whereas roots of cotton cannot, and the yield of cotton grown following bahia grass is often improved. Lal, Wilson, and Okigbo^[63] recommended growing *Stylosanthesguiansis* on Alfsoils in Nigeria. Growing cover crops can increase biological activity of earthworms and thus improve soil physical conditions or tilth, through the addition of organic matter and the formation of root channels.^[65,66,73,74] The beneficial effects of legume covers are greater in soils that have been subjected to low levels of compaction.^[70]

CONCLUSION

Use of large and heavy farm equipment increases risks of reduction in crop yields by 5–75% due to soil compaction. Effects of compaction on plant growth and yield depend on soil, crop, and climatic conditions. Compaction increases soil strength that adversely affects root growth and reduces crop yields. Compaction in the plow layer is related to contact pressure of the tire, whereas in subsoil, it is related to total axle load. Depth of compaction increases as both the soil moisture content and axle load increase. Strategies of managing compaction include soil and tillage management. This can be accomplished through the use of no till, controlled traffic system, crop rotations, mulching, incorporation of deep-rooted leguminous crops in rotation, and periodic chiseling. Alleviation of soil compaction can increase yields by 20–70%.

Croplands

B.A. Stewart

*Department of Agricultural Sciences, West Texas A&M University,
Canyon, Texas, U.S.A.*

Abstract

Production of food and fiber depends is focused on croplands. With the exception of land devoted to perennial crops, cropland is commonly referred to as arable land. Worldwide, cropland increased from about 365 Mha in 1700 to around 1.2 Bha in 1950. By 1990, it reached 1.4 Bha but there has been little or no increase since. Even though cropland expansion since 1950 has only been about 15%, production of cereals increased 2.9-fold and they occupy about 50% of the cropland. Therefore, most of the increased production between 1950 and today has resulted from higher yields rather than from expanded croplands that were the dominant factor prior to 1950. Irrigated area more than doubled since 1961, and consumption of synthetic nitrogen fertilizer increased more than tenfold. With the world population increasing and becoming more prosperous, projected food and fiber needs are expected to increase by 70% by 2050. Although there is potential for some increase in cropland area, particularly Africa and Latin America, increased production will remain focused on sustainable intensification of existing cropland.

INTRODUCTION

Croplands are used to produce food, fiber, and other products. Depending upon one's definition, the term "croplands" can include harvested croplands, land with perennial crops such as orchards and vineyards, pasture, land with failed crops, and areas idled in a particular year either for production reasons or through government programs. Cropland is often considered synonymous with arable land, but arable land statistics may exclude cropland devoted to permanent crops such as orchards. Statistics used in this report were obtained from Food and Agriculture Organization (FAO) data reported as arable land (FAOSTAT). Cropland devoted to pasture is intensively managed land that supports forage such as improved grasses or a mixture of grasses and legumes. Pasture land is very different from rangeland, which infers to unplowed areas where native grasses, forbs, shrubs, and trees are used for forage. Rangeland is included in agricultural land but not in cropland.

CROPLAND IN THE UNITED STATES

Cropland occupies about 155.1 Mha or 17% of the nation's land area (Table 1). This is a decrease from 19.7% in 1961. Government programs have often had the most significant effect on how much cropland is actively used and, in some cases, how it is used. Since the mid-1950's, area of cropland idled by U.S. Government programs has ranged from 0% to a high of nearly 20% with a high of 31 Mha in 1988. As part of the 1985 Food Security Act, the U.S. Congress established the Conservation Reserve Program (CRP) that

pays producers to take highly erodible land out of production. These areas are placed under 10- to 15-year leases and seeded to grass or trees. By 1993, almost 14 Mha of cropland had been taken out of production. Although some land enrolled in the program has been put back into production, other land has been placed into the program and about 12 Mha was in the program in 2012. Prior to the CRP, government programs that idled cropland were explicitly designed to control or stabilize the amount of crops produced. Urbanization has also significantly reduced cropland area and losses continue at the rate of about 400,000 ha annually.^[1]

The amount of crops and livestock produced in the United States more than doubled between 1948 and 1997,^[2] even though the amount of cropland was declining slightly (Table 1). The average agricultural productivity during that period increased 1.9% per year. The rate of growth has been somewhat less since 1997 but still increasing.^[3] The productivity increase was the result of farm inputs such as fertilizers, improved breeding, pesticides, and other capital investment. Irrigation also played a major role. Only about 15% of the cropland is irrigated but accounts for approximately 40% of the total value of crops produced.^[4] Irrigated areas dominate the production of several major crops, including rice with 100% irrigation, orchards 79%, and vegetables 66%.^[5]

Irrigation in the United States increased by more than 40% between 1961 and 1980 but has increased little since. It has actually decreased slightly since 1990 (Table 1). Perhaps more striking is the shift in irrigated area from western states to eastern states. Between 1982 and 2012, irrigated area in the western 17 states decreased from 84%

Table 1 Land area and use in the United States (FAOSTAT data).

	1961	1970	1980	1990	2000	2012
	Millions of hectares					
Land area	915.9	915.9	915.9	915.9	916.2	914.7
Agricultural land	447.5	434.4	428.2	426.9	414.4	408.7
Arable land	180.6	188.7	188.8	185.7	175.4	155.1
Irrigated land	19.0	21.7	25.0	26.9	27.0	26.4

of the total irrigated area to 72%. Irrigated area in the 17 western states actually decreased from 16.7 to 16.4 Mha.^[6]

CROPLAND IN THE WORLD

According to the FAO of the United Nations, there are about 1.4 Bha of arable land in the world (Table 2). It was

earlier estimated that the global extent of cropland increased from about 365 Mha in 1700 to around 1.2 Bha in 1950.^[7] Since 1961, however, the increase in arable land area has been relatively. From 1961 to 1990, arable land area in the world increased less than 10%, and there has been no increase since (Table 2). During the same time period, cereal production increased 2.9-fold. More than 50% of the arable land is dedicated to the production of cereals. Wheat (*Triticum aestivum*), maize (*Zea mays*), and rice (*Oryza sativa*) are the dominant cereals and occupied 15.5%, 12.8%, and 11.6% of the arable land in 2012. Cereals are of extreme importance because humans get about 48% of their calories from grains.^[8] In 2013, worldwide production of cereals totaled 2780 Mt of which 716 Mt was wheat, 741 Mt was rice, and 1018 Mt was maize.^[9] Historically, wheat was produced in the largest quantity followed by rice and then maize. Maize has become the dominant cereal grain because increasing prosperity in developing countries is resulting in changing diets that

include more animal-based products. About 66% of the global maize production is used for animal feed. The figure is higher for developed countries, which in 2000 used about 76% of the maize for animal feed, and lower (about 56%) for developing countries. Rice is consumed almost exclusively by people and Asia contains a staggering 89% of the world's harvested rice area.^[10]

CROPPING INTENSITY

A simple measure of how intensive cropland is used is the cropping intensity index. This is defined as the annual harvested area expressed as a proportion of the total cropland area (land in use plus fallow). For example, some cropping systems require a portion of the production area to be placed in fallow every year resulting in a cropping intensity index less than 1. In comparison, some irrigated areas can produce up to three crops per year from the same physical area and have a cropping intensity of 3. An extensive study of the increasing global crop harvest frequencies was conducted.^[11] It is generally assumed that crop production is increased either by expanding the area of standing cropland or by increasing intensification on existing croplands through the use of increased fertilizer, irrigation, mechanization, and improved seed varieties. The study^[11] focused on a third way of using the existing standing cropland, where appropriate, more frequently each year through multiple cropping, leaving less land fallow, and having fewer crop failures. The analysis showed that between 1961 and 2007, this third way contributed to 9% increase in global crop production, and the ratio of annually harvested land to standing cropland increased from 0.78 to 0.89 between 1961 and 2011. The study concluded that the 28% increase in global crop production between 1985 and 2005 was due to a combination of increasing harvested area about 7% and increasing average yields about 20%. In summary, the study attributed roughly a quarter of crop production increases to changing harvested area and the remaining three quarters to increasing yields.

IRRIGATION AND FERTILIZERS

As already stated, most of the increased crop production that has occurred since 1961 has been due to increasing crop yields. Although many factors contributed to higher yield, increasing irrigation area and fertilizer use have been of extreme importance. Irrigation area doubled worldwide between 1961 and 2012 and even more than doubled in Asia (Table 2). This removed water as the major constraint in many areas and made chemical fertilizers particularly effective. Clearly, nitrogen (N) and phosphorus (P) fertilizer uses became dominant factors in increasing cereal production, and China and India, the two most populous nations, were able to produce grain at rates faster than the

Fig. 1 Worldwide use of synthetic N fertilizer and production of cereal grains.

Source: Data from Smil.^[12] ©1999 and FAOSTAT.

population growth rate (Table 2). In 1961, these countries used less than 8% of the N fertilizer and less than 2% of the P. In 2012, they used 52% of the N fertilizer and 50% of the P fertilizer. China alone used 38% of the N and 36% of the P fertilizers.^[9] Synthetic N fertilizer production by the Haber–Bosch process became readily available following World War II that ended in 1945, and N fertilizer coupled with expanding irrigation area dramatically increased grain production as shown in Fig. 1. During the period from 1961 to 2012, cereal production increased threefold worldwide but in Asia where 60% of the population resides, cereal production increased fourfold (Table 2). Expansion of irrigated area is becoming increasingly difficult and costly so enhanced intensification of production on existing areas will be a primary focus.

SOIL DEGRADATION

With the focus on increasing intensification of croplands, there must also be enhanced attention on guarding against soil degradation. A 2010 report stated that of the 77% (837 Mha out of 1094 Mha) of the world's cropland area that is affected by water erosion, 83% (457 Mha out of 548 Mha) of the land prone to wind erosion, 97% (132 Mha out of 136 Mha) of that subject to nutrient mining, 94% (72 Mha out of 77 Mha) affected by salinization, and 83% (5 Mha out of 6 Mha) of that prone to acidification, occur in developing countries.^[13] These are also the regions where 99% of the projected increase in world population is expected to occur. Furthermore, farming communities in developing countries consist of resource-poor and small-size (<2 ha) landholders who use extractive farming practices involving litter or on off-farm input. Maintaining the amount and quality of cropland will require the use of sustainable management systems such as conservation agriculture and restoration practices to restore degraded lands. The principles of conservation agriculture are direct planting of seeds, permanent soil cover by crop residues and cover crops, and crop diversity.

CROPLANDS EXPANSION

The area of arable land increased slowly between 1961 and 1990 but has shown little change since 1990 (Table 2). Although there is some potential for expanding cropland, this is partially offset by losses due to urbanization and soil degradation. At the same time, the world population is expected to reach 9.1 billion by 2050 and food demand expected to increase by 70% more than in 2010 because of increasing prosperity in developing countries resulting in changing diets that include more animal products.^[9] The FAO states that despite the fact that 90% of the growth in crop production is projected to come from higher yields and increased cropping intensity, arable land will have to expand by around 120 Mha in developing countries, mainly in sub-Saharan Africa and Latin America. Arable land in use in developed countries is expected to decline by some 50 Mha, although this could be changed by the demand for biofuels. Sustainable cropping systems that not only control soil and water erosion but also improve soil quality and protect the environment must be accepted and practiced worldwide.

Abstract

Periodic flooding during the growing season adversely affects crop growth and productivity, with the exception of flooded rice, in many areas of the United States and the rest of the world. Tolerance of anoxia and hypoxia has been used synonymously with the tolerance of flooding stress. Tolerance of field flooding appears to be much more complex than tolerance of artificially induced hypoxia and anoxia. Contrary to the injury seen in flooded fields, soybeans can thrive in stagnant water. Soybean, therefore, is much more tolerant to excessive water and a lack of oxygen than previously expected. The reasons underlying the dramatic differences between responses to flooding in the greenhouse and flooding in the field are not known.

INTRODUCTION

Periodic flooding during the growing season adversely affects crop growth and productivity, with the exception of flooded rice, in many areas of the United States and the rest of the world. Soil can become flooded when it is poorly drained or when rainfall or irrigation is excessive. Other terms, such as soil saturation, waterlogging, anoxia, and hypoxia, are also commonly used to describe flooding conditions. Flooding causes premature senescence, which results in leaf chlorosis, necrosis, defoliation, reduced nitrogen fixation, the cessation of growth, and reduced yield. The severity of the flooding stress is affected by many factors, including flooding duration, crop variety, growth stage, soil type, fertility levels, pathogens, and flooding conditions.^[1] In general, stream flooding, characterized by the overflow of rivers or creeks into a flood plain, is more damaging than the lowland flooding, characterized by inadequate surface drainage and slow soil permeability of depressional areas. Sediments carried by stream flooding, when deposited on the leaves of flooded plants, can cause severe wilting and plant death within 24 hours of the stress. Flooding can be further divided into either waterlogging, where only the roots are flooded, or complete submergence, where the entire plants are under water. While plants develop adaptive mechanisms to allow them to survive long-term waterlogging, most plants die within 1 or 2 days of submergence.^[1]

The lack of oxygen has been proposed as the main problem associated with flooding.^[2] Indeed, tolerance of anoxia and hypoxia has been used synonymously with tolerance of flooding stress. During the last decades, a great deal of information has been accumulated from research on the molecular, biochemical, and physiological responses of plants to the lack of oxygen rather than to flooding per se.^[3–5] However, tolerance of field flooding appears to be much more complex than tolerance of artificially induced hypoxia and anoxia. Contrary to the injury seen in flooded fields, soybeans can thrive in stagnant water in the greenhouse, and soybeans grown in hydroponic medium continuously bubbled with nitrogen gas, where the dissolved oxygen level was not detectable showed no symptoms of stress.^[6] Soybean, therefore, is much more tolerant to excessive water and a lack of oxygen than previously expected. The reasons underlying the dramatic differences between responses to flooding in the greenhouse and flooding in the field are not known. However, growth reduction and yield loss in flooded fields could arise from root rot diseases, nitrogen deficiency, nutrient imbalance, and/or the accumulation of toxic levels of carbon dioxide (CO₂) in the root zone. Indeed, the levels of CO₂ commonly found in flooded soil (30%) severely caused leaf chlorosis and reduced plant biomass of soybean, a flood-susceptible crop, but not of rice, a flooding-tolerant crop (VanToai, unreported data).

MORPHOLOGICAL AND ANATOMICAL ADAPTATION TO FLOODING STRESS

One important morphological change associated with flooded roots is the formation of aerenchyma tissue, which contains continuous gas-filled channels connecting the root with the shoot. Other morphological changes, including hypertrophy and the formation of lenticels, adventitious roots, and pneumatophores, have also been observed in many plant species.^[7] Flooding can also change the direction of root growth. Roots of tomato and sunflower plants become disgeotropic or negatively geotropic under flooding conditions instead of positively geotropic.^[7] The changes in orientation of roots under flooding conditions enable them to escape stress from the reduced oxygen availability by growing closer to the better aerated soil surface.

PHYSIOLOGICAL, BIOCHEMICAL, AND MOLECULAR ADAPTATION TO FLOODING STRESS

Rice cultivars that showed rapid leaf and sheath growth during submergence did not survive as well as cultivars that did not elongate. Tolerant cultivars appeared to conserve carbohydrates in the shoots and roots during submergence.^[8] Upon removal of the stress, tolerant rice cultivars are able to recover more rapidly and suffer less plant mortality.^[9] An adequate supply of sugar is needed for corn root tips to survive anoxic and hypoxic stresses.^[10] The lack of oxygen induces a set of anaerobic proteins in roots to allow plants to cope with the stress.^[11] These stress proteins are enzymes of either glycolysis, glucose metabolism, or fermentation.^[10,12]

GENETIC VARIABILITY IN FLOODING TOLERANCE

Flooding tolerance is usually defined as minimal or no yield loss. According to VanToai et al.,^[13] waterlogging for 4 weeks during the early flowering stage reduced the average grain yield of 84 U.S. soybean cultivars by 25%. Yield reduction, however, varied from 9% in the most flooding tolerant cultivar to 75% in the most flooding susceptible cultivar. Flooding tolerance can also be defined as high yield under flooding stress. According to this definition, the most flooding tolerant variety in this study produced 3.7 Mg ha⁻¹, while the least produced 1.27 Mg ha⁻¹. When the cultivars were ranked for flooding tolerance based on both definitions, 7 of 10 most flooding tolerant cultivars were the same, and 7 of 10 least flooding tolerant cultivars were also the same. Thus, the two definitions of flooding tolerance, either high yield under flooding or minimal yield difference between non-flooded and flooded conditions, appear to be compatible. Flooding tolerance is independent from non-flooded yield indicating that genetic

variability for flooding tolerance exists and could be improved through plant breeding and selection.

Studies of submergence tolerance of rice showed that the unimproved landraces FR13A, Janki, and FR43B had survival values ranging from 41% to 51% after 10 days of submergence, while only 2–4% of elite cultivars (IR74, IR48, and IR68) survived.^[9]

IMPROVING FLOODING TOLERANCE BY TRADITIONAL PLANT BREEDING

Tolerance of flooding in wheat (*Triticum aestivum* L.) and rice (*Oryza sativa* L.) is a quantitative trait controlled by a small number of genes.^[9,14] Using the submergence tolerant landraces FR13A, Janki, and FR43B as donor parents, rice breeders at the International Rice Research Institute at Los Baños in the Philippines have developed an experimental rice line (IR49830-7-1-2-2) from crosses with the short stature, high-yield IR lines, which produced as much as 4880 kg ha⁻¹.^[9] The result showed that submergence tolerance can be incorporated into improved, high-yielding cultivars to raise the productivity in submergence-prone areas.

IDENTIFYING FLOODING TOLERANCE LOCI AND IMPROVING FLOODING TOLERANCE BY MOLECULAR PLANT BREEDING

Xu and Mackill^[15] identified a single submergence tolerance locus, *Sub1*, that controls about 50% of the variation in submergence tolerance of rice. During the last few years, molecular marker aided selection has been used successfully for the breeding of crops with improved quantitative traits.

VanToai et al.^[16] identified a single DNA marker that was associated with improved plant growth (from 11% to 18%) and grain yields (from 47% to 180%) of soybean in waterlogged environments. The identified marker was uniquely associated with waterlogging tolerance and was not associated with maturity, normal plant height, or grain yield. Near isogenic lines with and without the flooding tolerant marker have been developed and are being field tested under waterlogging conditions to confirm the association of the marker with the tolerance of soybean to waterlogging stress.

IMPROVING FLOODING TOLERANCE BY GENETIC TRANSFORMATION

Flooding induces or accelerates plant senescence in tobacco, tomato, sunflower, carrot, barley, peas, wheat, maize, and soybean. The most obvious visual symptom of flooded plants under stress is the yellowing of leaves followed by necrosis due to premature senescence. Within 1 day of flooding, the concentration of the antiaging

hormone, cytokinin, in sunflower xylem sap declined sharply to a very low level.^[17] In order to test if enhanced endogenous cytokinin production could improve flooding tolerance, Zhang et al.^[18] generated transgenic plants containing a gene coding for cytokinin biosynthesis. Four transgenic *Arabidopsis* lines were chosen for cytokinin and flooding tolerance determinations. The levels of cytokinin were similar between wild-type and transgenic plants in the unflooded treatment. After 5 days of waterlogging, the cytokinin increased 3 to 10 times in transgenic plants as compared to wild-type plants. In three independent experiments, all four transgenic lines were consistently more tolerant to soil waterlogging and complete submergence than wild-type plants. The results indicated that endogenously produced cytokinin can regulate senescence caused by flooding stress, thereby increasing plant tolerance of flooding. This study provides a novel mechanism to improve flooding tolerance in plants.^[18]

In summary, while the lack of oxygen has been used interchangeably with flooding stress, tolerance of field flooding is more complex than tolerance of anoxia and hypoxia. The use of molecular plant breeding and genomic transformation to improve flooding tolerance in crops is promising to be successful.

Cultivation: Raised-Bed

Kenneth D. Sayre

*International Maize and Wheat Improvement Center (CIMMYT),
Mexico City, Mexico*

Abstract

The raised-bed system of cultivation has been used since time immemorial and continues to play an important role in modern agriculture in both dry land and irrigated production systems. Raised beds have provided a means to help ameliorate the adverse effects when excess water leads to waterlogged conditions that hamper growth and development of most crops. They also provide a mechanism for the efficient application of irrigation water by furrow irrigation when properly managed. It is obvious that raised-bed cultivation systems can play an even more important role if appropriate crop management practices are developed that allow both dramatic reductions in tillage as well as opportunities to retain crop residues on the soil surface and if the needed implements are developed that allow farmers to more easily apply the technology. It is of particular importance that this technology be made readily accessible to small-scale farmers in developing countries.

INTRODUCTION

Indigenous farmers have used raised-bed cultivation systems for centuries. These include the chinapas or floating gardens used in the Valley of Mexico long before the Spanish conquest, the waru warus or caballones, large, raised embankments (in some cases more than 4 m wide by 20 m long), used at high elevations near lake Titicaca in Bolivia and Peru and which closely resemble similar structures used in Ethiopia on poorly drained Vertisols, the “deep ditch-high bed systems” found in the Pearl River basin in China and the mound planting systems used by numerous traditional farmers in Africa, Asia, many Pacific Islands, and the Americas together with numerous other raised-bed examples.^[1] There are several features common to traditional, raised-bed planting systems. They have been widely used to modify wetlands allowing agricultural production, but they have also been used to provide drainage in areas with either persistent or sporadic periods of excess rain that lead to waterlogged conditions. In addition, age-old raised-bed or mound-planting systems have been widely used for many root and tuber crops such as cassava (*Manihot esculenta*, Crantz), yams (*Dioscorea* sp.), sweet potatoes (*Ipomea batatas*, Lam.), taro (*Alocasia* sp.), and potatoes (*Solanum tuberosum*, L.), which is likely related to associated soil conditions that are less favorable for development of many soil-borne diseases associated with poor drainage.^[2]

Raised-bed planting systems, however, have also been used in water-limited situations. The Kofyar people of the Jos Plateau in Nigeria, e.g., enclosed ridges by “tying the ridges” with small dykes to trap water so that

after a rain their fields appeared to be checkered with pools of retained water for later crop use instead of being lost as run off.^[3] A more widely used application of raised beds in many semiarid/arid areas is planting crops on beds/ridges that are formed between furrows that are then used to supply irrigation water. This system has been used in dry regions such as Central Asia and China where irrigation systems were developed in conjunction with the production of row-planted crops such as cotton (*Gossypium* sp.) and has been widely used in the arid, Western United States.

NEED AND ECOLOGICAL NICHE FOR RAISED-BED CULTIVATION SYSTEMS

Therefore, the origin and use of raised-bed cultivation systems have traditionally been associated with water management issues either by providing opportunities to reduce the adverse impact of excess water on crop production through direct drainage, by offering a “raised platform” that allows crops to maintain their roots in unsaturated soil above the level of standing water, or, in contrast, by providing efficient irrigation water delivery to the fields for crop production in semiarid/arid regions. In most cases, the traditional use of raised-bed cultivation systems has involved considerable use of tillage operations (by hand, draft animals, or machinery) as a part of normal preparation to make the beds before planting the next crop. However, there were exceptions to these practices such as the chinampas in Mexico and some of the systems used in the Pearl River Valley in China, which used essentially no tillage combined with

Table 1 Suitability of raised bed cultivation systems for different agro-ecological niches.

Agro-ecological niche	Conventional-till beds with residue removal or incorporation	Permanent beds with surface residue retention
Gravity, furrow irrigated systems	Highly suitable	Highly suitable
High rainfall, dry land systems with water-logging/poor drainage	Suitable	Highly suitable
Low rainfall, dry land systems with season rainfall	Suitable with tied ridges	Highly suitable
Low rainfall, dryland systems using stored soil moisture	Possibly not suitable	Probably suitable

mulching of crop residues on the bed surface. For systems such as the waru warus used in the highlands of Peru/Bolivia, the form and structure of these large, raised beds were maintained as permanent beds with only minimal, superficial tillage.^[1] Table 1 provides a simple classification of different agro-ecological niches where bed planting may have relevance, especially when considering the possible use of permanent beds with surface-retained crop residues.

MODERN APPLICATIONS OF RAISED-BED CULTIVATION

As most crops are very intolerant to waterlogged soil conditions, there are many examples in modern agriculture that have applied raised-bed cultivation to ameliorate problems created by excess water for both dry land and irrigated conditions. In dry land production systems in Australia, e.g., the use of wide, raised beds (1.5–3 m wide depending on machinery) has been found to alleviate serious water logging following episodes of excess rainfall in Victoria, whereas in Western Australia wide, raised beds have proven useful where water logging occurs with even nominal rainfall on the prevalent, duplex soils that are characterized by extremely poor water infiltration. Yields for a wide variety of crops including wheat (*Triticum aestivum*, L.), barley (*Hordeum vulgare*, L.), canola (*Brassica* sp.), lupins (*Lupinus* sp.), faba beans (*Vicia faba*, L.), and oats (*Avena sativa*, L.) have been markedly increased compared to conventional flat planting as a result of 1) prevention of water logging that allows better root aeration; 2) an increase in the amount of plant available water because of more robust root systems; 3) more optimum planting time provided by more timely field access through better drainage and new opportunities to reduce crop turnaround time by reuse of the same bed; and 4) reduction in soil compaction through restricting all machine wheel traffic to furrows between the beds, which provide a permanent guide for controlled traffic patterns.^[4] Where excess water is a problem and raised beds contribute to facilitating drainage, the width of the bed can be quite variable depending upon the methods

used to form and maintain the beds (machinery, draft animal, and or human labor) and on soil type to some extent.

At the other extreme of the moisture/rainfall spectrum is the use of raised beds in mainly semiarid/arid regions to provide irrigation water by furrow irrigation. Farmers located in the Yaqui Valley in the state of Sonora in northwest Mexico provide an exceptional example of the application of raised-bed cultivation with furrow irrigation over about 255,000 ha of irrigated land. During the past, more than 95% of the farmers have changed from the conventional technology of planting most of their crops on the flat with flood and basin irrigation to planting all crops including wheat, the most widely grown crop, on beds. Bed width ranges from 60–100 cm, center bed to center bed, and this narrower bed width facilitates the efficiency of furrow irrigation for most soil types.^[5]

A single row is planted on top of each bed for row crops such as maize (*Zea mays*, L.), soybean (*Glycine max*, L.), cotton, sorghum (*Sorghum vulgare*, L.), safflower (*Carthamus tinctorius*, L.), and dry bean (*Phaseolus vulgaris*, L.), one to two rows per bed are planted for crops such as chickpea (*Cicer arietinum*, L.) and canola, but two to four defined rows, spaced 15–30 cm apart depending on bed width, are used for wheat and other small grains. The farmers who grow wheat on beds obtain about 8% higher yields, use approximately 25% less irrigation water, and encounter at least 25% less operational costs as compared to those still planting conventional tilled wheat on the flat, using flood irrigation.^[5] Surveys that have taken place to track farmer adoption of bed planting in the Yaqui Valley have indicated numerous reasons for this change in crop management and are presented in Table 2.

Most farmers in the Yaqui Valley who have adopted raised beds continue to practice conventional tillage, destroying the beds after the harvest of each crop followed by tillage operations before new beds are formed for the succeeding crop, often accompanied by burning crop residues although some maize and wheat straw are used for fodder.^[5] However, there has been intense farmer interest in the development of new production technologies that will allow marked tillage reductions

Table 2 Farmer survey results concerning reasons for farmer adoption of raised bed planting systems in the Yaqui Valley, Sonora, Mexico.

1. Improves irrigation water management and irrigation water use efficiency by 25–30% as compared to flood irrigation.
2. Facilitates preceding irrigation, which provides an opportunity for initial weed control prior to planting and allows better crop stand establishment especially on soils prone to crust formation following irrigation.
3. Provides a more uniform drainage system that reduces standing water in parts of the field where prolonged waterlogged conditions can occur.
4. Establishes a defined, controlled traffic system by restricting machinery wheels and animals to the furrows between the beds eliminating compaction in the seeded area on top of the bed.
5. Facilitates field access allowing:
 - i. New opportunities both mechanical weed control and more efficient hand weeding for all crops but especially for wheat, thereby reducing herbicide dependence.
 - ii. Better prospects to band apply nutrients (especially nitrogen fertilizers) when and where they can be most efficiently used.
6. Usually allows use of lower seeding rates for small grain crops compared to conventional planting systems.
7. Usually reduces crop lodging, especially for small grains when compared to conventional, flat planting systems.

combined with retention of crop residues that may lead to potential reductions in production costs, improved water/input-use efficiency, and more sustainable soil management while allowing continued use of the furrow irrigation system.

RESEARCH AND DEVELOPMENT CHALLENGES

As bed planting provides a natural opportunity to reduce compaction by confining traffic to the furrow bottoms, the next step needed to reduce tillage and manage crop residues on the surface is to only reshape the beds as needed between each crop cycle following even distribution of the previous crop's residues. The seeding of two to four defined rows on top of the bed as opposed to the normal, solid seeding pattern has made it possible to include wheat and other small grains in the system (Fig. 1).

Obviously, there has been and continues to be an important implement modification and development activity associated with the evolution of permanent bed planting technologies in addition to the development of other agronomic management aspects. The furrow makers that farmers already use to make beds with tillage can be easily modified to reshape the permanent beds by simply attaching cutting disk coulters ahead of the furrow openers for residue management. Similarly, existing zero till planters for row crops such as maize and soybean can be easily adapted for planting on permanent beds into crop residues. However, no commercial zero till wheat planter is readily available that can plant two to four rows on wheat on top of 60–100 cm wide beds without tillage and into high levels of crop residues. More effort is needed to develop suitable permanent bed, small grain seeders. And a clear priority needs to focus on the development of appropriate implements, especially for small grains, so that these new

Fig. 1 Wheat and soybean planted on permanent beds under furrow irrigation with retention of crop residues.

permanent bed technologies can be extended to small-scale farmers.

CONCLUSION

The raised-bed system of cultivation has been used since time immemorial and continues to play an important role in modern agriculture in both dry land and irrigated production systems. Raised beds have provided a means to help ameliorate the adverse effects when excess water leads to waterlogged conditions that hamper growth and development of most crops. They also provide a mechanism for the efficient application of irrigation water by furrow irrigation when properly managed. It is obvious that raised-bed cultivation systems can play an even more important role if appropriate crop management practices are developed that allow both dramatic reductions in tillage as well as opportunities to retain crop residues on the soil surface and if the needed implements are developed that allow farmers to more easily apply the technology. It is of particular importance that

this technology be made readily accessible to small-scale farmers in developing countries.

Abstract

Soilless systems allow farmers to grow plants without soil. This can eliminate or reduce many problems associated with traditional cultivation on soil *in situ*, such as soil-borne diseases and pests, the related use of agrochemicals, and decline of soil structure and fertility due to continual cultivation of the same or related crop species. Although often associated with vegetables, soilless systems allow cultivation of many other plants, including flowers and ornamentals. In soilless cultivation, plant roots may grow either in porous media (substrates), which are frequently irrigated with a nutrient solution, or directly in the nutrient solution without any solid material. Soilless systems can be either open-loop or closed-loop cultivation systems. The latter, which involves reusing any drainage solution, can substantially reduce potential pollution of water resources by nitrates and phosphates, while contributing to an appreciable reduction in water and fertilizer consumption. Other general advantages of the soilless systems are as follows: 1) plant nutrition can be better controlled than in crops cultivated in the soil, 2) soil tillage and preparation are avoided, thereby increasing the potential length of the cultivation time, and 3) yields are increased. The major disadvantages of soilless culture are the high costs that are required for the initial installation, as well as the increased technical skills that are needed.

INTRODUCTION

Several civilizations have utilized soilless culture. Egyptian hieroglyphic records dating back to several hundred years B.C. describe the growing of plants in water without soil. Somewhere between mythical and historical fact, we find the hanging gardens of Babylon built around 590 B.C. by King Nabucodonosor II, as a gift to his wife Queen Amitis.

In the 11th century, in Mesoamerica, the nomadic Mexica tribe, one of the native tribes who later formed the Aztec empire, built the City of Tenochtitlan on the shores of Lake Texcoco. Artificial islands called chinampas were created by fencing in the shallow lake bed with wattle. In the Andes, the ancient Aymaras built their villages on floating islands, made of totora reeds (*Schoenoplectus californicus* ssp. *tatora*), over the Titicaca lake at 4000 m a.s.l. People lived out of fishing and crops grown on these islands.

On the other face of the earth, in Myanmar (Burma), vegetables and fruits were grown in large gardens that float

on the surface of the Inle lake. Following an ancient tradition, the beds of the floating gardens were made by creating rafts out of rushes and reeds (to make floating beds) and anchoring them with bamboo poles. People dredge up soil from the shallow bottom of the lake and pile it onto the rafts.

In this entry, we define “Culture: Soil-less” as the cultivation of plants in systems other than soil *in situ*, including hydroponics and other growing media or substrates. In soilless culture, either a liquid or aggregate medium is used. The term “hydroponics” described the growing of crops with their roots only in a liquid medium. Growing media are presented in another separate entry (p. 533).

OPPORTUNITY AND CHALLENGES OF SOILLESS CULTURE

Soilless culture offers significant advantages compared with cultivation in soil. Crop production becomes independent from soil characteristics and is possible even in areas with

poor soil structure or high salinity. The main reason for using soilless culture, however, is the reduction of soil-borne pathogens and the improved control over water and nutrient supplies.^[1] Other advantages, such as better environmental protection with closed systems and improved product quality through precise dosage of nutrients, are becoming more and more important.^[2]

The main characteristic of SCS is the restricted volume of rooting medium in comparison to soil-grown crops.^[1] Systems may be open or closed loop. In an open system, any excess irrigation is allowed to go to waste and is not recycled. In a closed system, any drainage is captured and recycled. Most hydroponic systems are inherently closed, but many systems based on solid materials were open. The installations are closed systems, which will likely become mandatory as the nutrient management planning is implemented in more countries. The nutrients used in these systems are applied as a complete nutrient solution.^[1] A closed-system demands improved water quality to prevent the buildup of unwanted ions. It also means that the composition of the nutrient top-up solution has to closely match the nutrient ratios absorbed by the crop. The nutrient top-up solution has been performed based on electrical conductivity measurement. This may be replaced by the use of specific ion sensors, if they are robust enough.^[3] Closed systems also increase the risk of spreading root diseases through the system, and consideration must be given to the treatment of the captured drainage water before the recycling process.^[4]

SYSTEMS WITHOUT A SOLID MEDIUM

Savvas et al.^[5] classified soilless culture and systems into water culture, which includes deep water culture, float hydroponics, nutrient film technique (NFT), deep flow technique, aeroponics, and substrate/aggregate culture (Fig. 1). The first deep water culture systems described by Gericke^[6] were not widely adopted, due to problems in adequately aerating the solution.^[7] Cooper^[8] devised a system in which the plants were grown in a recirculating nutrient solution in polyethylene gullies set on a sloped greenhouse floor. The plant roots developed in the shallow stream of solution in the gullies, hence the name NFT. The shallow stream was devised to overcome the aeration problem inherent in deep water systems.

Some leafy vegetables, such as lettuce, rocket, lamb's lettuce, and spinach, are successfully grown in floating hydroponics (Fig. 1d). In this system, plants are grown in polystyrene plates or other containers that float on the nutrient solution. The main advantages of this system are that 1) installation costs are low; 2) plants have constant access to water and the nutrient solution and a large buffer capacity for pH and nutrients; and 3) crops can be moved easily into the greenhouse; thus results in fast growth and an early harvest with more production cycles during the year. This

novel hydroponic system has been increasingly utilized commercially. In aeroponics, the roots are periodically sprayed with a fine mist of nutrient solution (Fig. 1a). The advantage is optimal aeration, but production costs are high. In addition to these systems, systems with a solid medium are used as well (Fig. 1c and e). Different irrigation systems, such as a row or a drip irrigation system, are used in this case (Fig. 2). For more information concerning growing media, refer to p. 533.

SOILLESS CULTURE AND YIELD

In soilless culture, higher yields can be achieved compared to soil cultivation due to an optimization of nutrients and water availability to the plants. In addition, the soilless cultivation enhances the early yield in crops planted during the cold season of the year, due to higher temperatures that can be maintained in the root zone during the day. For instance, Selma et al.^[9] showed that a growth period of 102 days was needed for fresh-cut lettuces (*Lactuca sativa*) to reach the same maturity stage in soil compared to 63 days in soilless culture. Also, soilless systems may increase water use efficiency over soil-based systems, i.e., the yield per unit of water applied.

However, crop yields can be affected by many factors such as a soilless culture system (i.e., type, substrate, and open or closed), water quality (i.e., sodium chloride content), composition of nutrient solution [i.e., electricity conductivity (EC), pH, and nutrient ratios], fertilization and irrigation strategies, climate conditions, and length of the growing season and management. EC of a nutrient solution, which is a measure of the total ionic content, is an important property of the nutrient solution and is commonly used to control the day-to-day supply of nutrients backed up by periodic analysis of the nutrient solution for levels of individual nutrients. The EC can be manipulated to influence yield and quality, and the optimum level may vary widely among different species.^[5]

SOILLESS CULTURE AND PRODUCT QUALITY

According to Gruda,^[2] soilless culture does not automatically guarantee high-quality products. However, some consumers are rather mistrustful with the vegetables produced in soilless cultivations. This attitude is mainly based on the assumption that the soilless cultivation of plants is based on the extensive use of “chemicals,” in contrast to plants grown in soil that acquire “natural substances.” However, this belief is not based on scientific knowledge. It is well known that higher plants need inorganic substances, mainly in ionic form, to satisfy their nutritional requirements. Thus, for instance, plants take up nitrogen (N) as NO_3^- and NH_4^+ . Any possible uptake of N in organic forms, e.g., amino acids, has a minor contribution to plant N nutrition. Organic N is generally to be converted into inorganic form

before it can be absorbed. Consequently, with respect to the quality of edible vegetable products, it is irrelevant whether the N contained in the plant tissues stems from organic

substances of the soil or from inorganic fertilizers. The only main factor influencing vegetable quality is the quantity of absorbed N and the way in which it is utilized in the plant

metabolism, which has an impact on the nitrate (NO₃)–N concentration in edible plant tissues. Both these factors are better managed in soilless cultures, because the small volume of the rooting medium applied in soilless cultures enables a more efficient control of the nutrient supply through the composition of the nutrient solution. Thus, reducing the NO₃–N concentration in the nutrient solution supplied to lettuce or other leafy vegetables for some days prior to harvesting may lower the NO₃[–] content in the leaves of the plants considerably, without a significant yield loss. Moreover, the pressure from root zone diseases is much weaker than in soil grown crops.^[5] Several studies confirm that soilless culture enables growers to produce vegetables without quality loss compared to soil cultivation. As a result, the need to use soil disinfecting chemicals is considerably reduced or eliminated in soilless culture. This carries obvious advantages for the quality of the produced vegetables. Last but not least, the taste of some fruits such as tomato, melon, etc. may be substantially improved in soilless culture by manipulating the total salt and nutrient concentration in the supplied nutrient solution. To obtain optimum results, cultural management must always be adapted to the specific production system being used.

Soilless culture offers more opportunities to control the yield and quality of the product than do conventional soil systems.

ECONOMIC CONSIDERATIONS

Soilless culture has to be economically viable, in order to be adopted. The data in Table 1 show that under greenhouse conditions in Northern Europe, yields and returns tend to be higher in soilless culture systems compared to traditional soil-based systems. This offsets higher costs and results in increased margins.

There is also evidence that the removal of soil sterilants such as methyl bromide will improve the adoption of soilless culture systems under a wider range of conditions.^[11]

CONCLUSION

A major advantage of soilless culture is that it provides a practically sterile root environment, free of pathogens, and independence from soil characteristics. As a result, yield is increased and product quality is improved. This has been

Table 1 An economic comparison between soil systems and soilless cultivation systems for different vegetable crops.

the case particularly when combined with the use of sophisticated control systems for nutrient supply and irrigation. The disadvantage is that soilless systems are generally expensive and require high qualified personal. Therefore, they have mainly found applications in the production of high-value pharmaceutical crops, fresh vegetables, ornamentals, and in few cases of some fruits.

Cycling: Carbon and Nitrogen (C/N)

Sylvie M. Brouder

Ronald F. Turco

Department of Agronomy, Purdue University, West Lafayette, Indiana, U.S.A.

Abstract

The demands on modern agriculture to provide ample food, feed, and energy coupled with anthropogenic (human)-driven global climate change have greatly increased the importance of understanding and managing the dynamics of soil carbon (C) and nitrogen (N) cycling (C/N cycling). The world's C and N supplies exist in a continuous and dynamic cycle, and key processes are constantly active in the soil beneath our feet. The amount of C in the top one meter of soil (the pedologic pool) is approximately 3.5-fold greater than that in the atmosphere, and this C helps soil to retain its structure and function including crop production and ecosystem stability. In contrast to C, the great majority of the earth's N is not in soil but in the atmosphere. However, most of the forms useful to plants are found in the soil. Plant productivity in natural systems is often N limited; in agriculture, farmers routinely supplement soil N with fertilizers and manure and, thus, perturb C/N cycles. The cycles of C and N in soil are linked and are controlled by microorganisms. As a result, microorganisms and their activity have a significant impact on some of our greatest challenges including sustaining food production and water quality and reducing soil emission of the greenhouse gases that drive climate change. This entry provides a new overview of the forms and locations of C and N in soil, emphasizes the biological factors controlling pedologic C/N cycling, and addresses how anthropogenic activities stress the soil ecosystem, potentially impacting its stability.

INTRODUCTION

Carbon (C) and nitrogen (N) exist in soils in both inorganic and organic forms. Globally, only 780 petagrams (Pg; 10^{15} g) of C are in the atmosphere while the top one meter of soil is estimated to contain approximately 2700 Pg of C, 57% of which is soil organic matter (SOM).^[1] In contrast, N in soil is less than one-hundredth of 1% of the N content of the atmosphere but, as with soil C, most soil N is in organic versus inorganic forms.^[2] The inorganic C and N forms in soils include the gases carbon dioxide (CO_2) and dinitrogen (N_2) in the air space of soil pores and soluble forms in soil water such as carbonates from the chemical breakdown or weathering of rocks and minerals (e.g., silicates and limestones) and nitrate (NO_3^-) and ammonium (NH_4^+) from the breakdown or mineralization of SOM. C and N occur in all living tissues: C in sugars, starches, lipids, and a staggering array of complex molecules and N in nucleic acids (DNA and RNA) and in amino acids that are assembled into proteins. Both C and N are an integral component of SOM, which is formulated from plant and animal residues in various stages of decomposition including particulates of various size fractions, dissolved OM in soil water, and humus or stable OM as well as the living biomass of soil microorganisms (e.g., bacteria and fungi).^[3] To a large degree, microorganisms control or drive global C and N (C/N) cycling. Even under relatively extreme environmental conditions, soil

C and N are in a state of constant flux where microbiology transforms C and N among an array of molecules and drives C and N movement between the soil and the surrounding air and water. The goal of this entry is to summarize the state-of-the-art knowledge on the microbiology of soil C/N cycling and discuss how human activities including agriculture are causing large perturbations in soil C/N cycles for which outcomes are uncertain but anticipated to continue to contribute to global climate change.

BACTERIA AND FUNGI CONTROL SOIL C/N CYCLES

The proportion of soil C and N in the biomass of soil microorganisms is surprisingly small (1.2% and 2.6%^[4]), given the importance of soil microbiology in C/N cycling. Soil bacteria are typically 1 μm or less in length and live in tiny colonies (only 100 or so cells per colony) found inside of soil aggregates and are typically attached to clay and silt fractions. However, while the actual bacteria are small in physical size, soils are rich in cell number, microbial diversity, and, consequently, metabolic abilities. A surface soil can contain greater than 4000 different microorganism communities (i.e., genomes) and can support as many as 10^9 (one billion) bacteria in one gram.^[5,6] Subsurface soils will tend to have lower population levels but will exceed 10^7 cells g^{-1} .^[7] Because bacteria are small but soil surface

area large, bacteria are found on less than 0.17% of the total surface area of SOM and less than 0.02% of the soil's mineral surface area.^[8] Further, soil bacteria are largely sessile (not freely moving) and prefer to adhere to surfaces using a form of electrostatic interaction (London-van der Waals forces) followed by a hydrophobic interaction, where the cells secrete a polymer that binds them to the surface.^[9] This binding reaction attaches bacteria and soil particles together, helping to create the soil structure. Water is the critical connecting force in soil, as it moves nutrients and oxygen from their sources to the sessile resident population [Fig. 1, process (P) 1]. The exact locations within soil colonized by bacteria reflect the availability of nutrients (typically embedded organic C) and a preference by bacteria for the small soil pores (between 0.25 and 6 μm diameter) associated with the microaggregate fractions.^[10,11] Analysis has shown that greater than 80% of soil bacteria are located within the soil's microaggregate (2 and 53 μm in size) fraction.^[12] Small pores offer an ideal location for bacteria as they allow for the passage of water, which carries nutrients and oxygen but blocks predators such as protozoa.

Fungi also contribute to soil C/N cycling, but fungi differ from bacteria in several important attributes. Soil fungi are resident on the outside of aggregates and are associated with larger organic materials and the coarse sand

fractions.^[13] More importantly, fungi are made mobile by extension of their hyphae and in doing so are the early colonizers and decomposers of fresh organic residues added to soil via natural and anthropogenic activities (Fig. 1, P 3). Fungi function by secreting a wide array of enzymes, which start many important soil processes. The combined abilities of residue colonization and enzyme secretion give fungi a critical role in initiating the C/N cycling processes in fresh residue additions to soil.

Continuous Soil C/N Cycling Requires Diversity in Organisms and Substrates

Soils and fresh additions of plant and animal materials present the resident microorganisms with a compositionally diverse array of organic substrates as potential energy and nutrient sources; genetic and associated functional diversity of the soil microbiology ensures ongoing soil C/N and other nutrient cycling in the ever-changing physical and chemical environments.^[14] Simplistically, nutrient cycling reflects two sets of processes by which microorganisms meet their need for (1) energy and (2) essential nutrients [e.g., C, N, phosphorus (P), and sulfur] to maintain or increase their biomass (cell numbers). Because both bacteria and fungi must assimilate nutrients across a membrane, organic

Fig. 1 Diagrammatic representation of the major C/N cycle soil processes. Left side shows C/N cycling at the terrestrial scale and right side is magnified to highlight cycling within the soil matrix.

substrates must first be solubilized into physically smaller fractions. In organic residues of plant origin, the cell walls composed of lignin and cellulose form a recalcitrant physical barrier to degradation. Fungi are one of a few kinds of organisms that can secrete the enzymes necessary to break down cellulose to glucose and the only known organism that can completely degrade lignin via in-place oxidation. Thus, initial decomposition typically involves hyphal extension and enzyme excretion into newly introduced organic material to release labile substances (Fig. 1, P 3). This release process is general and creates a pool of soluble materials including physically smaller C and N molecules such as simple sugars, amino acids, and proteins that can be accessed by other bacteria, fungi, and growing plants. Labile materials not immediately assimilated by fungi may be washed out of decomposing tissue by rainfall; once these substrates reach the soil, they are transported into the soil matrix in soil water and diffuse to the resident microorganisms inside and outside of the soil aggregates (Fig. 1, P 5).

Under most conditions, once soluble organic N molecules are transported into the soil matrix, they rapidly enter a multistep process that sequentially creates the inorganic N forms of NH_4^+ and NO_3^- . Proteins and other organics rich in N are acted upon by bacteria that produce ammonification enzymes that free ammonia (NH_3) from C; in water, NH_3 dissolves to form NH_4^+ (Fig. 1, P 7). The $\text{NH}_4\text{-N}$ can be assimilated by soil bacteria or plant roots (Fig. 1, P 6). When soil water concentrations of NH_4^+ are high, excess NH_4^+ may adsorb onto negatively charged soil surfaces where it is held until soil water NH_4^+ concentrations dissipate and the NH_4^+ diffuses back into solution (Fig. 1, P 8). Additionally, most soils are rich in chemoautotrophic bacteria. Whereas heterotrophic bacteria and fungi power their assimilation of organic C by the oxidation of organics, chemoautotrophic bacteria rely on the oxidation of inorganics (e.g., NH_3) and free CO_2 as their energy and C nutrition sources, respectively. Under aerobic conditions, chemoautotrophic (e.g., nitrifying) bacteria oxidize NH_4^+ , consume CO_2 , producing NO_3^- instead of CO_2 as an end product (Fig. 1, P 9). Nitrate is both water soluble and non-reactive with the negatively charged soil surface; thus, once in the $\text{NO}_3\text{-N}$ form, N is not only available for assimilation by plants and microorganisms but also highly susceptible to loss from the soil system via the physical process of leaching with excess rainfall (Fig. 1, P 10).

It is important to note that different organisms and processes dominate when water from rainfall or flooding causes soils to become anoxic, and these anaerobic processes have significant impacts on soil emission of greenhouse gases. When soil water content is high, macropores in soil are filled with water and O_2 consumption by aerobic bacteria, and plant root respiration (energy derived by electron transfer to O_2) exceeds the O_2 replacement rate from the soil atmosphere. As soil O_2 is depleted, the activity of anaerobic microorganisms that can use electron acceptors other than O_2 will increase. Provided adequate C substrate,

many soil bacteria can use $\text{NO}_3\text{-N}$ instead of O_2 as a terminal electron acceptor in the energy formation process with N_2O and N_2 as end products, a process called denitrification (Fig. 1, P 11). Alternatively, in fermentation, bacteria use the organic substrate itself to replace O_2 as the oxidizing agent; an important fermentation end product is methane (CH_4). Not only is denitrification an important loss pathway for soil N but products of both denitrification and fermentation have also been identified as potent greenhouse gases. The global-warming potentials on the individual molecule basis are 321- and 12-fold that of CO_2 for N_2O and CH_4 , respectively (100-year timeframe).^[15]

An additional subset of microorganisms is critical to the soil C/N cycle. While most soil microorganisms and plants cannot use the wealth of N_2 in the soil atmosphere, some have the ability to convert or “fix” the inert N_2 gas into ammonia NH_3 . This biological N fixation (BNF) has three forms: it can be independent (free living), associative, or symbiotic with respect to higher plants. Free-living N_2 -fixing bacteria are widely distributed and ubiquitous in the soil, but their contributions to terrestrial N is comparatively minor ($<1 \text{ kg ha}^{-1} \text{ yr}^{-1}$) as these organisms lack easy access to C substrates for energy to drive the extremely energy-intensive fixation process. These bacteria fix N for their own metabolic needs but, when they die and decompose, the fixed N becomes available to plants. Some of these free-living bacteria live on the soil surface and can photosynthesize and have been estimated to add $10\text{--}38 \text{ kg N ha}^{-1} \text{ yr}^{-1}$.^[16] Much larger contributions come from soil microorganisms that can colonize root surfaces and invade plant tissues to gain more direct access to energy sources provided by plants. The largest contributions occur when soil microorganisms form true symbiotic relationships with plants such as occurs in legumes. Here, molecular dialogue between the soil microorganism and the plant root leads to the development of a specialized structure or nodule in the plant root to house the N_2 fixation process (Fig. 1, P 4). In the resulting symbiosis, plants and microorganisms achieve a relatively direct exchange of C for N. Symbiotic N fixation can contribute 24 to 250 kg N ha^{-1} in a growing season^[17] and, when plant tissues die, this organic N is returned to the soil. Estimates of total annual contributions of BNF to fixed N in terrestrial ecosystems range from $107^{[18]}$ to $195^{[19]}$ teragrams (Tg; 10^{12} g) N yr^{-1} .

NATURAL VERSUS ANTHROPOGENIC CONTROLS OF C/N CYCLES

Among all the nutrient elements essential for soil microorganisms to grow, C and N are required in the largest quantities and are typically the most limiting in soils of natural systems; consequently, the general state of soil microbiological communities in their natural condition is one of

repressed activity. Higher plants capture their C from atmospheric CO₂ with photosynthesis (Fig. 1, P 2) but, as with soil microorganisms, N must be acquired from soils (Fig. 1, P 6) and is required in higher quantities than any other soil-derived nutrient. Thus, N also constrains plant productivity in unmanaged ecosystems. Over the past several decades, human activities have increasingly perturbed pedologic C/N cycles by physically disturbing soils and/or by increasing quantities of C and/or N in labile form in the soil matrix thereby enhancing the overall activity of microorganisms and increasing opportunities for C and N loss from soils. Chief among anthropogenic activities known to disrupt previously stable cycles are: (1) conversion of natural to managed systems with the goal of growing selected plant species (e.g., crops) with enhanced net primary productivity and (2) the common agricultural practices of soil tillage and N fertilization.

In natural ecosystems, equilibrium exists between what happens when fresh organic residues are added and the genesis and decay of the resident soil humus. The rates of C/N cycling are modulated both by the physical environment and by the composition of added organic materials. Whereas labile substances such as simple sugars, amino acids, and proteins decompose rapidly, subsequent, slower rates of decomposition involve microorganisms attacking increasingly recalcitrant materials. Soil humus, the stable components of SOM that, by definition, bear no resemblance to the floral, faunal, or waste material of origin, is relatively resistant to biodegradation and includes materials derived from lignins, tannins, cutins, and so on.^[20] In the absence of fresh residues, SOM serves as the major nutrient source for resident flora. However, as SOM is difficult to degrade and is N limited, the function of microorganisms is slow when they are constrained to this nutrient source. Without fresh additions, soil microorganisms are “starved” and waiting for the arrival of nutrient (C, N, and P)-rich materials; as a general rule, new additions from an N-rich residue such as from an annual legume will decompose faster as compared to an equivalent mass of lignin-rich residues from tree branches and trunks.

Major physical determinants of cycling include the soil temperature and moisture regimes. Soil temperatures fluctuate daily and seasonally, especially at the soil surface. Cold or freezing temperatures can drastically slow or halt activity of microorganisms, often without killing them, while temperatures above 35°C not only halt activity but may also kill heat-sensitive organisms. Likewise, drought and low soil water status can restrict microbiology and desiccate microorganisms causing dormancy while soil flooding and anoxia slowdown the growth of organisms that prefer aerobic conditions. However, niche differentiation is the hallmark of successful microbiological communities: heat-tolerant will proliferate at the expense of heat-sensitive soil microorganisms under high soil temperatures and, as discussed

in the preceding text, anaerobic will take over from aerobic organisms with prolonged soil flooding.

Anthropogenic Factors Disrupting C/N Cycles: Land Conversion, Tillage, and N Fertilizers

Long-term stability in soil function is a direct result of centuries of buildup of SOM by soil microorganisms. However, the impacts of human activities related to agriculture can result in SOM degradation at rates that far outpace the comparatively slow but constant rates of SOM accumulation in natural systems. Ruddiman^[21,22] dates anthropogenic soil losses of C as CO₂ to 8000–10,000 years ago with the beginnings of settled agriculture; soil C losses as CH₄ date to 5000 years ago and the introduction of paddy rice production. Estimates are that net anthropogenic emissions to the atmosphere total approximately 9.1 Pg C yr⁻¹, 82% of which comes from fossil fuel emissions; the remaining 1.6 Pg C yr⁻¹ has been sourced to land use conversion (deforestation and biomass burning), agricultural cultivation, and associated erosion.^[1] A meta-analysis of impacts of land use change on soil C showed that C stocks in the top 60 cm of soil decreased an average of 50% when soils were converted from native forests to row crop agriculture.^[23] In contrast, converting forest to pasture did not negatively impact soil C stocks, but converting pastures into crops was as detrimental as direct conversion to crops from native forests. Conversion of cropland back to pasture or secondary forest restored some or all soil C, respectively.

Tillage, the mechanical disturbance of soil, is an agricultural practice that dates from the first settled agriculture.^[24] It is a proven technology for conditioning the soil for agricultural crops including breaking up soil layers that are too hard and impede root exploration, mechanically controlling weeds that compete with crops for water and nutrients, incorporating nutrients, manure, and residue, controlling residue-borne pests and pathogens, and aerating the soil. Incorporation promotes rates of decomposition of residues of the soil surface by mechanically breaking down residues into small pieces, mixing residue fragments with soil, and enhancing the surface area of the residue directly in contact with the decomposer microorganisms in the soil. However, potential negative impacts are equally numerous.^[25] Tilled soils that are not covered with a vigorously growing crop or even a thick mat of fallen residue are highly susceptible to erosion by wind and rainfall. Further, pulverization and compaction of the surface and underlying soil layers, respectively, can lead to reduced water infiltration and poor root development that reduce yields. The implementation of tillage on previously pastured and forested land typically results in dramatic losses of soil C.^[23] The implementation of surface residue conservation and no-tillage crop management can restore some soil C but not under all conditions,^[26] and the value of these practices as a universal solution is uncertain.^[27]

Unlike tillage, the application of large amounts of fertilizer N has strong linkages to global climate change. The objective of fertilization in agriculture is to ensure crop productivity and is not limited by competition with soil microorganisms over inadequate mineral N supplies. Early agriculture could rely on only modest amounts of additional N from manures or legumes. Dramatic accelerations of soil C/N cycling in intensively managed agricultural systems are linked to the 1908 discovery of the Haber–Bosch process for high temperature and pressure conversion of N_2 to NH_3 . Subsequent commercialization of the process revolutionized the production and thus availability of N fertilizers. Estimates of global N inputs into agricultural land are 213 Mt (10^6 t) $N\ yr^{-1}$ of which 47% is fertilizer.^[28] In contrast, livestock manures and BNF by leguminous crops account for only 16% and 28%, respectively, of annual global N inputs; cereals, primarily wheat, rice and maize, account for 55 Mt $N\ yr^{-1}$ of fertilizer N. These fertilizer applications are associated with large increases in crop CO_2 capture but also with the acceleration of rates of C/N cycling including losses from soil. The negative impacts of N fertilizer on global N cycles are known to be substantial and range from eutrophication of aquatic systems to acid rain and ozone depletion.^[29] However, implications of an altered N cycle for other biogeochemical cycles are much less certain and include a complex array of climate-relevant feedbacks.^[30] Gruber and Galloway^[30] identify reducing uncertainty in our understanding of coupled C/N cycle perturbations as essential to improving global climate change projections.

CONCLUSION

With reference to ecological function, Becking and Beijerinck concluded more than a century ago “everything is everywhere, but the environment selects.”^[31] Anthropogenic activities change the environment, and any form of agriculture should be viewed as a selective pressure on soil that will cause the equilibrium of the natural C/N cycle to shift. Soil microbiology, with its great diversity of organisms, will respond with strategies optimizing the use of both quantities and forms of C and N introduced by soil management. For agriculture, the challenge for the production of major staple crops that underpin global food security remains the design of management systems that appropriately balance the trade-offs between yield objectives, soil biology, and long-term soil stability and sustainability of ecosystem function. The challenge is particularly complex, as the nature and magnitude of trade-offs are site and soil specific. As we are managing soils to maximize crop yield, the soil biology is constantly responding to our interventions. For example, when reduced forms of N are applied, a subset of soil microorganisms will increase cell numbers and activity to oxidize the material and create the soluble forms such as NO_3^- -N. These soluble forms can be either

leached out of the soil causing water pollution or transported to reduced locations where denitrifying microorganisms consume them and emit greenhouse gases. Conversely, when residues high in C but low in N are applied, soil microorganisms will tie up and use all forms of available nutrients, limiting the amount of N and P available to growing plants. Food security goals that seek to double agricultural yields on all arable lands will require enhanced quantities of plant-available nutrients. More efficient nutrient management strategies to increase crop production while minimizing impacts on air and water quality and global climate change have been frequently identified as critical to achieving global food security. Much of our research investment has gone toward exploring genetic aspects of crop yield and resource (e.g., N and water)-use efficiencies. Research on functional roles of soil microorganisms and their responses to management has lagged and must be elevated to the prominence of plant genetics, as the soil’s resident microorganisms are the systems-level control point for many key processes governing use efficiency of soil resources.

Debris Flow

Jau-Yau Lu

Department of Civil Engineering, National Chung Hsing University, Taichung, Taiwan

Abstract

Debris flow is a rapidly moving two-phase gravity flow with a high content of wide-gradation solid particles. Debris flow hazard mitigation is very important because the flow often causes heavy loss of life and property. This entry discusses the classification, initiation, movement and deposition, and hazards mitigation of the debris flow. Based on materials contained in the flow, debris flow can be classified into the following three types: viscous debris flow, non-viscous debris flow and mud flow. In general, physical processes of debris flow consist of initiation, transportation, and deposition of solid particles. Conditions relating to the initiation of debris flow include 1) availability of loose solid material; 2) steep slope gradient; and 3) heavy rainfall. The first two are the potential factors, and the third one is the triggering factor. Debris flow usually occurs near the upland areas with steep slope gradients, moves along gullies or channels, and decelerates rapidly once it reaches a gully or channel outlet where the slope abruptly levels off. The depositional area below the channel outlet is usually called “debris cone” or “debris fan.” One of the interesting characteristics during the transportation of debris flow is the accumulation of large boulders at the front of the flow. Absolute control over debris flows is rarely feasible either physically or economically. The most commonly accepted measures for reducing debris flow damage can be divided into two categories, i.e., structural and non-structural measures.

INTRODUCTION

Debris flow is a rapidly moving two-phase gravity flow with a high content of wide-gradation solid particles. It usually occurs in gullies or on sloping land near the upstream areas. Debris flow has a strong erosive force that erodes the gully bed or banks as it moves downstream. Debris flow hazard mitigation is very important because the flow often causes heavy losses of lives and properties.

The debris flow problem has been recognized as a very critical problem worldwide. Fig. 1 is an example showing the disaster caused by the debris flow of April 29, 2000, at Chia-Yi County in central Taiwan. This debris flow event was induced by a devastating earthquake (100-year return period), 7.3 on the Richter scale, in central Taiwan on September 21, 1999. The earthquake caused the exposure of a large amount of loose soil on the sloping land. With a dry season from October through February, debris flow did not occur until the wet season the following spring. The total amount of rainfall for the storm (April 28–29, 2000) that triggered this particular debris flow event was 152 mm.

Literature review related to the mechanics, predictions, and hazards mitigation of the debris flow can be found in Chien and Wan,^[1] Jan and Shen,^[2] Chen,^[3] Takahashi,^[4] Chen,^[5] Wiczorek and Naeser,^[6] Rickenmann and Chen,^[7] Chen and Major,^[8] Proceedings of the Fifth International Conference on Debris-Flow Hazards Mitigation: Mechanics, Prediction, and Assessment.^[9]

CLASSIFICATION OF DEBRIS FLOW

Debris flow can be classified according to the composition or the causes and processes of occurrence. The causes of occurrence include rainfall, snowmelt, earthquake, volcanic eruption, and destruction of lake.

Based on materials contained in the flow, debris flow can be classified into the following three types:^[1,10] 1) viscous debris flow; 2) non-viscous (stony, waterborne) debris flow; and 3) mud flow (muddy debris flow).

Viscous debris flow, which carries materials ranging from fine clay to large boulders, is the most common type of debris flow. The debris flow shown in Fig. 1 is an example of the viscous debris flow. Both non-viscous (stony) debris flow and the mud flow can be considered as two extreme cases of the viscous debris flow. Non-viscous (stony) debris flow has very few fine particles. It usually runs smoothly as a single and continuous event. On the contrary, viscous debris flow is characterized by the intermittent pulsing. A single event may include several dozen pulses.

Mud flow mainly carries sediment finer than coarse sand (2 mm). However, the flow sometimes also carries a small amount of rock fragment. After an intense thunderstorm on August 25, 1967, a mud flow of more than 50,000 cubic yards occurred in the 1.5-square mile Second Creek Basin in Nevada. It damaged properties and roadways and polluted Lake Tahoe.^[11]

Non-viscous debris flow and mud flow can be considered as the extreme cases of viscous debris flow. Table 1

compares the material and physical characteristics for different types of debris flow.^[1,10]

INITIATION OF DEBRIS FLOW

In general, physical processes of debris flow consist of initiation, transportation, and deposition of solid particles. Conditions that trigger the initiation of debris flow include 1) availability of loose solid material; 2) steep slope gradient; and 3) heavy rainfall.^[1] The first two are the potential factors, and the third one is the triggering factor for the formation of a debris flow.

Table 1 Comparison of the material and physical characteristics for different types of debris flow.

Type	Material	Physical characteristics
Viscous debris flow	Carries fine clay to large boulders, wide gradation	Intermittent pulsing, an event may include several dozen pulses Usually laminar flow
Non-viscous debris flow (stony or waterborne debris flow)	Large boulders carried by water or slurry	Single and continuous event Usually turbulent flow Accumulation of large boulders at the head due to particle collision
Mud flow	Finer than coarse sand (<2 mm), with limited amount of rock fragment	Violent turbulent mixing May be caused by the volcanic eruption

Fig. 2 View looking upstream of the 1996 debris flow near Hsin-Yi bridge.

Source: Photo by S.H. Tseng.

The loose solid material may be due to the prior land-falls, landslides, typhoons, earthquakes (e.g., Fig. 1), glaciers, or rock weathering. The production of loose material is also related to the geological conditions. The gravitational force associated with steep slopes is an important driving force for the initiation of debris flow. An analysis of 150 debris flow gullies in Tibet showed that the debris flow occurred in gullies with slopes of 10–30%. In Japan, most of the debris flow occurred in gullies with slopes greater than 15% or 27%. These observations have been incorporated into a model that predicts the critical slope for the initiation of debris flow.^[12]

An intense rainstorm is the triggering factor for the initiation of debris flow as illustrated in Fig. 1. Fig. 2 shows the debris flow of July 31, 1996, near Hsin-Yi bridge (180 m long), Nantou County, Taiwan. The debris flow was caused by a 24-hour rainfall of 745 mm from Typhoon Herb, which broke the local 200-year maximum daily rainfall record. The amount of deposited material was so large that the surface of the deposited material almost reached the lower surface of the bridge deck (5–6 m high from the original channel bottom).

Essentially, three types of debris flow initiation predominate.^[10] The first two types are due to erosion of channel bed and landslide. The third type is the destruction of a natural dam by the overtopping of river water or by the collapse of the dam body itself under the effects of the seepage water and the hydraulic pressure.

Several landslides occurred near the Tsao-Ling area in central Taiwan, which is approximately 40 km south of the epicenter for the earthquake (7.3 on the Richter scale) of September 21, 1999. An upstream impoundment of water, with an estimated total storage volume of about 43,000,000 m³, was produced. In fact, this location has a long history of landslides induced by either earthquake or heavy rainfall, resulting in the impoundment of water and subsequent breach outflow causing downstream damage and loss of life. For example, landslides in December 1941

and August 1942 produced a total impoundment about 170 m deep with a volume of about 120 million m³ by October 1942 (after heavy rainfall), which eventually failed during overtopping (4 m depth) in May 1951, resulting in 437 deaths and associated damage.

MOVEMENT AND DEPOSITION OF DEBRIS FLOW

Debris flow usually occurs near the upland areas (upper reach of a watershed) with steep slope gradients, moves along gullies or channels (middle reach of a watershed), and decelerates rapidly once it reaches a gully or channel outlet (mouth) where the slope abruptly levels off. The depositional area below the channel outlet is usually called “debris cone” or “debris fan.”

Fig. 3 shows an aerophoto of the debris flow disaster caused by Typhoon Toraji at Shang-An Village, Shueili Township, Nantou County, Taiwan, in 2001. One can clearly see the “debris fan” at the channel mouth.

One of the interesting characteristics during the transportation of debris flow is the accumulation of large boulders at the front of the flow. The phenomenon can be explained by Bagnold's^[13] dispersive pressure concept; i.e., the dispersive force is proportional to the square of particle diameter. With this vertical sorting mechanism, the coarse particles gradually move toward the water surface. Since the maximum flow velocity occurs near the water surface in an open channel flow, the large boulders proceed faster than the smaller particles and gradually accumulate at the front of debris flow.

The mechanics of debris flow are very complex. Models that account for the rheological properties of the debris flow material and processes have been developed by

researchers.^[2,3,14] The debris flow has been modeled as a Bingham substance, as a viscoplastic fluid, or as a dilatant fluid. The flow velocities of a steady 2-D debris flow can be obtained using various models with the assumption of a uniform mixture (continuum).

Mathematical models have also been developed to predict the snout profiles of constantly advancing debris flows on hillslopes.^[4,15] The deposition process of debris flow can be modeled based on the theory of mass and momentum conservation.^[4,16,17] The proper prediction of the deposition areas (e.g., evolution of debris cones) and deposition depths is very useful for disaster and damage prevention.

HAZARDS MITIGATION

Absolute control over debris flows is rarely feasible either physically or economically. There are many different methods for debris flow hazard mitigation. The most commonly accepted measures for reducing debris flow damage can be divided into two categories, i.e., structural and non-structural measures.^[5–9,18]

The structural measures include different types of dams (e.g., consolidation dams, dams with holes such as grid-type dam and slit dam), retarding basins, and diverting and deflecting walls.^[19] Selection of a proper structure depends on the type of debris flow (e.g., stony debris flow vs. mud flow) and the area to be protected (i.e., upper reach, middle reach, or debris cone of a watershed).

The watershed management practices, such as revegetation of barren areas and reforestation, are non-structural debris flow countermeasures. Other non-structural methods include hazard zoning, relocation of endangered properties, and temporary evacuation of people in the debris flow–threatened areas on the basis of warning systems.

Debris flow mitigation projects often utilize a combination of several measures based on both physical and economical considerations. For example, many landslides occurred on the hillslopes and mountainous areas in central Taiwan due to the devastating earthquake of September 21, 1999 (7.3 on the Richter scale). As it was a dry season from October 1999 through next February, the revegetation and reforestation were not immediately effective after the earthquake. The cost and the construction time also prohibited the selection of structural measures. Therefore, hazard zoning, relocation, and emergency evacuation were the most suitable means of debris flow mitigation until other long-term measures became effective or could be implemented.

Improvement of the numerical models is needed to accurately predict the movement and deposition of the debris flow. Collection of more field data for the debris flows is also extremely important for calibrating the numerical models and to increase the reliability of the real-time warning systems.

CONCLUSION

Absolute control over debris flows is rarely feasible either physically or economically. The most commonly accepted measures for reducing debris flow damage can be divided into two categories, i.e., structural and non-structural measures. Debris flow mitigation projects often utilize a combination of several measures based on both physical and economical considerations. Improvement of the numerical models is needed to accurately predict the movement and deposition of the debris flow. Collection of more field data for the debris flows is also extremely important for calibrating the numerical models and to increase the reliability of the real-time warning systems.

Degradation

Rosa M. Poch Claret

José A. Martínez-Casasnovas

University of Lleida, Lleida, Spain

Abstract

Soil degradation is defined as the loss of the soil's capacity to develop its functions; e.g., support for plant growth, hydrological regulation of watersheds, environmental filtering, and support for buildings, among others. The best known of the soil degradation processes are soil erosion, compaction, alkalization, salinization, pollution, acidification, nutrient depletion, and organic matter loss. The entry reviews the concept of soil degradation and its historical evolution, listing the processes and causes of soil degradation. In addition, the concept of soil conservation is also introduced, as the measures to maintain the soil quality or the techniques to maintain land productivity, reducing soil degradation in the broad sense. Other terms, often considered synonymous to soil degradation, such as desertification of land degradation, are also discussed.

INTRODUCTION

Soil degradation is defined as the loss of the soil's capacity to develop its functions; e.g., support for plant growth, hydrological regulation of watersheds, environmental filtering, and support for buildings, among others. Former approaches to soil degradation, from a productivity or agronomic point of view, have evolved to an environmental one in the last three decades. A more comprehensive approach considers the soil to be a part of the land and part of a socioeconomic, historical, and cultural reality. The environmental point of view enables other degradation processes to be accepted—not only those processes affecting soil's intrinsic characteristics (changes in the physical, chemical, biological soil properties or agricultural use) but also those processes due to externalities. The best known of these degradation processes are soil erosion, compaction, alkalization, salinization, pollution, acidification, nutrient depletion, and organic matter loss. There are other, less common factors that limit soil use, such as the lack of accessibility, natural disasters, and war and even cultural, socioeconomic, and historical limitations to proper use of the land. The increasing interest in sustainable land management is a result of the scarcity of land resources, together with the probable effects of global climatic changes. The soil in a sustainable system must keep its qualities by means of adequate use.

SOIL DEGRADATION: CONCEPTS AND EVOLUTION

Historical Perspective

The earlier definitions of soil degradation were based on the zonality concept,^[1–3] later, they are replaced by definitions

related to land use. Degradation means the loss of the soil's agricultural productivity, which according to Charman^[4] includes soil erosion, salinization, loss of chemical fertility, acidification, and structural degradation as the main soil degradation processes. Aveyard and Charman^[5] also stress the importance of the off-site effects and human impact on the degradation processes, which are the result of the mismanagement of the soil. These processes interact, as soil compaction due to traffic may result in the decline of ecological functions.^[6] Within the framework of land evaluation, degradation is then defined as *the decline in soil quality caused through its improper use by humans*.^[7] The Food Agricultural Organization (FAO)^[8] also points out the importance of the rate at which the process occurs: Degradation may not necessarily be continuous in time but can occur during a short period between two stages of ecological equilibrium. Six types of soil degradation that follow this concept are presented, together with the units of measurement that assess the rate of the process: 1) water erosion ($\text{Mg ha}^{-1} \text{yr}^{-1}$); 2) wind erosion ($\text{Mg ha}^{-1} \text{yr}^{-1}$); 3) excess of ions: salinization (electrical conductivities) and alkalization (exchangeable sodium percentage); 4) chemical degradation: acidification (ΔVyr^{-1}) and toxicity ($\Delta \text{ppm yr}^{-1}$); 5) physical degradation (Δpyr^{-1} ; ΔKsyr^{-1}); and 6) biological degradation (ΔOMyr^{-1}).

At the end of the 1970s, society's general awareness of the importance of the environment permitted an expansion of the concept of soil degradation, which is finally defined as *the loss of the soil's capacity to develop its functions in the environment*. These functions are based on soil being the natural substrate for plant growth, the regulator of the water regime of hydrological units, and the natural environmental filter.^[9] This definition allows an acceptance of processes affecting the land and its socioeconomic, historical, and cultural framework other than those related to

agricultural aspects. Degradation processes include those limiting soil uses in the short, medium, and long terms, not merely those caused by inappropriate agricultural or forestry use among others. Polluting soils, urbanization, mining activities, watershed mismanagement, flooding, global climatic change, loss of accessibility, and even minefield installation in war zones are also recognized as human activities or natural phenomena leading to land degradation. All of these processes have been better assessed with the increase of soil knowledge, the use of models to foresee its behavior, and land information management, particularly geographic information systems.

The concept of degradation has evolved to consider other aspects of the environment, and soil degradation is considered as a particular case of land degradation. For example, the Global Environment Outlook^[10] considers as forms of land degradation, soil erosion, nutrient depletion, water scarcity, salinity, and disruption of biological cycles. Other soil degradation processes, in addition to the traditional approach, have been recognized, e.g., at European Union level,^[11] as erosion, organic carbon decline, soil biodiversity decline, compaction, contamination, salinization and sodification, soil sealing, and landslides. From these, the first six processes are closely linked to agriculture.^[12]

Nevertheless, sometimes the functions developed by the soil are mutually exclusive. It is not expected that soil along a river can be used for agriculture and act as a green filter simultaneously or serve as the support for human settlement and become an area of water table recharge as well. Is a saline soil with a specific halophytic community a degraded soil? Or, must a value be given to the genetic background of the plants growing there? The application of conservation agriculture to African agroecosystems^[13] is a good example of the conflict between competing goals in land management. In fact, soil degradation processes are often assessed from an anthropocentric point of view, by the evaluation of the possible use humankind can make of it, instead of considering its impact on the environment in the long run.

Soil Conservation and Degradation

The concept of soil conservation has also evolved along with soil degradation. Although defined as the group of measures used to prevent degradation, conservation was originally used only as a synonym for antierosion measures. It was formerly defined as *measures to maintain the soil layer*^[11] or *the techniques to maintain the productivity of the land, reducing erosion*.^[14] Other management techniques, such as liming, salt control practices in irrigated land, bioremediation techniques in polluted soils, reduced tillage and no-tillage, among others, are also included when defining soil conservation in the broadest sense.

Other environmental definitions of soil conservation implicitly include the concept of sustainability and refer

more to the conservation of a land devoted to a specific use than to the intrinsic conservation of the soil itself. Soil conservation consists of the *optimal rational use of the natural resources and the environment, taking into account*

Table 1 Soil degradation processes. Interactions between them are not included.

Intrinsic processes
Degradation of the physical fertility
Compaction
Sealing
Crusting
Structural degradation
Soil loss: water and wind erosion
Land movements by civil engineering or urbanization (levelings, landfills, and landcuts)
Mining
Resource consumption; urbanization on highly productive soils
Water excess
Hydromorphism
Impermeabilization by urban use
Sodification and alkalization
Degradation of chemical fertility
Loss of nutrients: Leaching
Extraction by plants (nutrient mining)
Runoff
Immobilization
Acidification, including that due to acid rain
Salinization
Sodification and alkalization
Pollution
Degradation of biological fertility
Loss of organic matter
Extrinsic processes
Loss of accessibility: loss or damage of roads
Change of ownership regime
Loss of material or human resources
Conversion to risk area: natural disasters
Volcanic and seismic activity
Floods
Fires
Human diseases
Wars
Development of inadequate agricultural policies
Climatic fluctuations
Illiteracy
Cultural traumas

Table 2 Causes of soil degradation.

Agricultural practices
Improper agricultural practices
New cultures in former rangeland
Monocultures
Traffic of machinery
Excessive irrigation schemes and schemes without drainage systems
Inadequate or overfertilization
Inappropriate or excess of tillage
Overgrazing
Deforestation
Generation and application of residues to the soil
Natural causes
Climatic changes
Earthquakes and active volcanoes
Floods
Fires
Industrial activities
Mining
Residue applications
Buildings and civil engineering structures
Socioeconomic causes
Human pressure
Urbanization of cropland and marginal agroecosystems
Lack of education
Inadequate ownership system
Tourism
Political causes
Environmental policies
Social and cultural policies
Economical and market policies
Wars

The use of the term desertification was generalized after the Nairobi Conference in 1977, when desertification was defined as the diminution or destruction of the biological potential of the land, and can lead ultimately to desert-like conditions. It is an aspect of the widespread deterioration of ecosystems and has diminished or destroyed the biological potential, i.e., plant and animal production, for multiple-use purposes at a time when increased productivity is needed to support growing populations.^[22]

The previous definition has a clear, economical approach applicable to developing countries and assumes anthropic causes in the process, derived from a population increase causing a high demographic pressure in the system. It does not specifically refer to arid environments, although the lack of water and the lack of the environment's storage capacity are conditions similar to those of a desert.

Thus, because soil is the component of the ecosystem with the largest water storage capacity, it is evident that soil degradation is one of the main causes of desertification. In this sense, Porta et al.^[23] indicate that desertification may be better defined as the *soil degradation that goes beyond the tolerance limits, generally due to a human intervention*. The authors advise to restrict the use of term to degradation processes taking place in marginal areas near deserts. The use of the general term *land degradation* would be more appropriate for environments other than arid or semiarid.

Soil degradation problems can be successfully addressed through a driving forces–pressures–states–impacts–responses analysis.^[24] Some applications can be found in Porta and Poch^[25] and Emadodin et al.^[26]

Degradation: Biological

Ibrahim Ortaş

Department of Soil Science and Plant Nutrition, University of Cukurova, Adana, Turkey

Abstract

The soil component of the agro system consists of plant roots, microflora, fauna, organic matter, and the abiotic geochemical matrix. Soil can be a sink for atmospheric carbon dioxide and mitigate the “greenhouse effect.” Soil is a complex living and fragile system that must be protected and managed for its long-term stability and productivity. Soil degradation has been defined as the loss of a soil’s capacity to produce crops and also as the antithesis of soil resilience and quality, which describe biological degradation as the decline in soil organic matter and biomass carbon, a decrease in diversity and activity of soil flora and fauna, or the indiscriminate use of chemicals and pollutants. The increasing loss of species in the past few decades has been a consequence of habitat destruction and direct exploitation of plant populations. As a result, most plant species that are unique to a defined geographic location (called) have disappeared simultaneously with most rhizosphere organisms, such as mycorrhizal fungi and Rhizobium bacteria, causing the decline in soil biological diversity. Mycorrhizal fungi are the largest existing symbiotic plant communities in plant roots, which are an essential part of healthy plant growth, survival, and soil biological quality, particularly in desertified landscapes, because of their essential role in sustaining the vegetation cover. In natural soils, beneficial rhizosphere microorganisms such as mycorrhizae are abundant and readily available to plants for their health and soil quality. Desertified and mismanaged ecosystems are very fragile and subject to progressive disturbance of the vegetation cover and rapid degradation of soils.

INTRODUCTION

The soil component of the agro system consists of plant roots, microflora, fauna, organic matter, and the abiotic geochemical matrix. Soil can be a sink for atmospheric carbon dioxide (CO₂) and mitigate the “greenhouse effect.”^[1] In this system so far, soil has taken second place with respect to plants. Bethlenfalvay and Schüepp^[2] stated that the importance of soil is recognized not only as an agricultural resource base but also as a complex, living, and fragile system that must be protected and managed for its long-term stability and productivity. Soil degradation has been defined as the loss of a soil’s capacity to produce crops and also as the antithesis of soil resilience and quality.^[3] Bedano, Dominguez et al.^[4] describe biological degradation as the decline in soil organic matter (SOM) and biomass carbon (C), a decrease in diversity and activity of soil flora and fauna, or the indiscriminate use of chemicals and pollutants.

The human relationship with soil started more than 15,000 years ago with the ancient civilizations in Anatolia and Mesopotamia, located in the Fertile Crescent of the Tigris and Euphrates river basins. Throughout the early history of agriculture, human use of land for farming and grazing had little effect on the depletion of soil properties. As the human population increased and an agriculture became more settled over the 19th and 20th centuries, however, cultivation practices such as tillage, intensified

conversion of native soil to agriculture, and a large amount of native microorganisms have disappeared, resulting in depletion of organic matter and decreasing soil fertility. Harvesting of residues and deforestation gradually accelerated the problem. Increasing loss of species in the past few decades has been a consequence of habitat destruction and direct exploitation of plant populations. As a result, most plant species being unique to a defined geographic location (called) have disappeared simultaneously with most rhizosphere organisms, such as mycorrhizal fungi and Rhizobium bacteria, causing the decline in soil biological diversity.

Mycorrhizal fungi are the largest existing symbiotic plant communities in plant roots, which are essential part of healthy plant growth, survival, and soil biological quality, particularly in desertified landscapes, because of their essential role in sustaining the vegetation cover. In natural soils, beneficial rhizosphere microorganisms such as mycorrhizae are abundant and readily available to plants for their health and soil quality. However, loss of mycorrhizal fungi is common in mismanaged soils with excess use of chemicals and practices of tillage and irrigation. Desertified and mismanaged ecosystems are very fragile and subject to progressive disturbance of the vegetation cover and rapid degradation of soils. High disturbance and degradation generally result in the loss or reduction of soil microorganisms such as mycorrhizal propagules. Azcon-Aguilar et al.^[5] indicated that under the high degree of

degradation of the ecosystem, diversity of arbuscular mycorrhizal fungi (AMF) present in the soil is rather low. If the mycorrhizal inoculum potential is low or ineffective, it may limit the successful reestablishment of native plants as a result of the decline of soil organic carbon (SOC) and productivity and increase in biological degradation.

FACTORS THAT AFFECT SOIL BIOLOGICAL DEGRADATION

Soil Management

Soil management practices significantly impact soil aggregation^[6] and C dynamics. Ortas, Akpınar, and Lal^[7] have shown that compared to inorganic fertilizer, organic fertilizers, including mycorrhizal inoculation, contributed considerably to soil aggregation and soil C sequestration. Aggregates encapsulate SOC and reduce the rate of its decomposition.^[8] Similarly, plant roots and AMF hyphae provide physical protection to soil C against microbial decomposers through aggregation.^[9] Oades^[10] indicated that the SOC encapsulated within soil aggregates has a lower decomposition rate than that located outside of aggregates.

Soil Tillage Accelerates Soil Biological Degradation

Agricultural machinery, mainly heavy tillage, often causes soil compaction, which increases bulk density and alters soil pore size distribution, and movement of air, water, and nutrients. Soil aggregation is one of the important soil characteristics which mediates many soil chemical, physical, and biological properties and improves soil quality and sustainability.^[11] These aggregates also encapsulate soil organic compounds and reduce the rate of their decomposition.

Heavy tillage results in the loss of SOM through mineralization of C due to breakdown of soil aggregates. Through the mineralization of SOM, more CO₂ is released to the atmosphere.^[12] On the other hand, reduced tillage has been shown to result in increased SOM^[13] and soil microbial biomass levels.^[14] Under field conditions, the soil microbial biomass C and the bacterial functional diversity as well as the microbial activity were good indicators of soil quality, which were positively correlated with SOM contents.^[15]

North American farmers have been widely using a technique known as conservation tillage or zero tillage to reduce the degradation problem. This technique employs special machinery and herbicides to plant crops with minimal disturbance to the soil surface (Fig. 1). Studies since the 1980s have indicated that soil disturbance by tillage reduced the effectiveness of mycorrhizae symbiosis.^[16] The extraradical or external soil hyphae of AM and plant roots associates frequently to produce sticky materials that cause soil particles to adhere, creating small aggregates that

Fig. 1 Heavy plowing and tilt direction tillage reduce SOM levels more than other tillage activities.

Source: Photo Ortas, 2014.

impart structural properties to soil, allowing for improved aeration and water percolation, as well as stability.^[17]

Soil disturbance can reduce the infective potential of AMF in several ways: 1) propagules may be physically damaged, spores may be crushed, and the external hyphae network and colonized root fragments may be disrupted; 2) disturbance may alter the physical, chemical, or biological environment of the soil, which in turn prevents the colonization by or germination of AM propagules; 3) soil disturbance may eliminate host plants, leading to changes in the C supply available to the fungi. C fixation through photosynthesis is the biggest contributor to increasing soil organic pool in through soil profile.

Tisdall, Smith et al.^[18] studies clearly document the role of mycorrhizal hyphae on facilitating the flow of C compounds to the bulk soil, which is an essential process for soil stability. After the development of the soil structure, the aggregates enhance C and store nutrients, thus providing microhabitats for soil organisms.

The Effect of Chemicals on Soil Biological Degradation

Long-term applications of phosphorus (P) and nitrogen (N) and micronutrient fertilizers may reduce the abundance of indigenous AMF and other soil organisms. The highest concentrations of P, zinc (Zn), and copper in maize were observed in nonreduced and reduced tillage treatments concurrently with the highest hyphal densities,^[19] preserved against destruction by tillage. The results have clearly shown that the greater rates of P fertilizers were not required in reduced tillage systems, compared to conventional causing greater soil disturbance.^[20]

High concentrations of heavy metals were determined to adversely affect the size, diversity, and activity of microbial populations in soil, and as a results, soil microbial biomass is reduced. Pesticide, herbicide, fungicides, and nematocides are used to control a wide variety of organisms on many crops; unfortunately, often the control they provide is

erratic. This erratic behavior is not always predictable and has been associated with the chemical, physical, and biological degradation of soils.

CROP MANAGEMENT

Fallowing

Crop rotation and fallow systems have been observed to significantly affect the diversity and the function of mycorrhizal fungi and the loss of root colonizing AMF that benefit the plant by increasing uptake of P in the semiarid cropping systems of Australia and the United States.^[21] Decline in AM colonization and soil propagule densities were the results of fallowing and correlated with plant P and Zn deficiency Ellis.^[21]

Crop Rotation

Humankind's knowledge of the benefit of crop rotation dates back more than 3,000 years. Available literature links its effect on yield to increasing AM colonization. The so-called green revolution inducing the trend of monoculture has been responsible for the increased use of chemical and the control of weeds, insects, and plant diseases.

It has been demonstrated that rotation not only affects mycorrhiza formation in general but also can affect SOC content and also species of AMF associated with different crops. The effect of the conventional rotation and cover crop on protection of soil biological degradation is vital. Many farmers are using cover crop to protect soil sustainability. Results revealed that under the low-input systems, cover crops tended to increase SOC in Mediterranean vineyards.^[22] Under cover crop conditions, soils have higher populations of rhizosphere organisms and mycorrhizae spores and a greater diversity of mycorrhizal fungi than did the conventional farming systems.

Stubble Burning and Grazing

Crop residues are a major source of SOM. Sometimes crop residues are disposed of by burning in an attempt to ease

tillage and also control weeds and soil-borne diseases (Fig. 2). Residue burning significantly reduces microbial activity and diversity, thereby reducing microbial immobilization of N and sulfur, resulting in short-term availability of these nutrients. Chan and Heenan^[23] indicated that under Australian conditions, crop residues burning and tillage are two of the major processes responsible for the decline of SOM content in cropped soils and the resulting soil degradation. Stubble burning causes oxidative losses of N and C. Through this management, SOM content is reduced.

Depletion of SOM is exacerbated on continually cropped arable land because of the burning of crop residues. Forest clearing followed by maize/cassava cropping in Ghana is a good example with a decrease in the C content of the soil from 2.19% to 1.50% in 8 years.^[24] Harvest residues are usually burned on the surface or used as forage, household fuel wood, or construction material before soil cultivation for second crop sowing. This, together with overgrazing, removes large quantities of organic matter from the soil, causing biological degradation by altering the turnover rate of the organic matter. Serious negative environmental impacts of harvesting and overgrazing result, inducing land degradation reflected by increased soil compaction and erosion and decreased soil fertility. This leads to the biological degradation of the soil, with decreased indigenous mycorrhizae and other beneficial soil organisms—the “must” for success for sustainable agriculture, conventionally restored by pasture development. Grazing management is necessary to maintain the ecological function in order to preserve the SOM contents. Heavy grazing strongly affected soil properties indirectly through a change in shrub composition and cultivation, resulting in a decrease in soil N and organic matter.

Depletion of Soil Organic Matter

Most of the soils of many regions of the world have low SOM ranging from 1% to 2%.^[25] Thus, SOM concentration has a strong influence on soil fertility and yield. The low SOC stock and poor soil fertility are attributed to harsh climate and soils of low inherent fertility. The stock of SOC plays a key role in the global C cycle and

Fig. 2 Stubble burning significantly reduces SOM content in soil surface.

Source: Photo Ortas, 2005.

strongly impacts soil biological fertility. The SOC stock is reduced by excessive tillage.^[26] Because of supraoptimal temperatures, high concentrations of calcium carbonate, and excessive heavy tillage, SOM decomposes rapidly and low soil fertility is rather common throughout the most of the world. The severe depletion of SOC is attributed to extractive farming practices and mismanagement of soil and crops.

Depletion of the SOM content is one of the major causes underlying the declining agronomic productivity in soils of the Mediterranean region.^[27] Degradation of organic matter is resulted in the release of large amounts of plant nutrients, particularly C and N. The accelerated soil degradation also depletes soil fertility and increases the emission of CO₂ and methane from erosion-induced transport of SOM.^[28]

SOIL RESILIENCE

Soil biological degradation can be restored by several methods: 1) recycling of organic wastes; 2) suitable soil and crop management reducing tillage; 3) grazing management; 4) increasing crop rotation; 5) better water management; 6) use of cover crops for enhancing SOM; and 7) use of beneficial soil organisms, such as mycorrhizal fungi and bacteria.

Agroforestry is being used to control soil biological degradation, for reforestation and to establish pasture. The latter, especially with deep-rooted perennial grassland, cover crops allow the sustainability of the soil to be regained by increasing the number of indigenous microorganism populations and thereby increasing C levels in the soil through organic matter.

CONCLUSION

Soil and crop management have significant effects on soil quality and protection. Protective agricultural practices are vital for sustainable life. Especially reducing tillage; less chemical fertilizer use; using cover crop, crop rotation, mulching; and using organic fertilizer are very important to increase SOC content.

The use of native and genetically engineered microorganisms holds considerable promise for increasing soil biological productivity. An understanding of the impact of agronomic practices on communities of mycorrhizal fungi and other rhizosphere organisms would help to ensure an opportunity for the utilization of the symbiosis and would contribute to the success of sustainable agriculture. It is important to appreciate that beneficial soil microorganisms are present and are an integral part of most conventional agriculture production systems. It is also important to identify how those benefits can be maximized to enhance agricultural sustainability.

Degradation: Chemical

M. Rifat Derici

Soil Science, University of Cukurova, Adana, Turkey

Abstract

Soil chemical degradation is undesirable changes in soil chemical properties such as pH, size and composition of cation exchange complex, contents of organic matter, mineral nutrients, and soluble salts. These changes that severely deteriorate the chemical fertility of soils may result in soil acidity, alkalinity, salinity, sodicity, and depletion of soil organic matter and plant nutrients, and lead to a decrease in soil productivity.

INTRODUCTION

Soils are continually undergoing natural chemical changes as a result of weathering. The combination of the weathering process with other factors, such as parent material, climate, biota, and topography, is responsible for the evolution of soil variety. The forces and factors affecting soil formation are always operational in a manner such that a static equilibrium state is never attained. However, the balance at any given time is highly sensitive to these factors, and a new equilibrium toward soil degradation may be the outcome when there are natural or man-made changes. Soil chemical degradation can be described as an undesirable change in soil chemical properties such as pH, size and composition of cation exchange complex, contents of organic matter, mineral nutrients, and soluble salts. Changes in one or more of these properties often have direct or indirect adverse effects on the chemical fertility of soils, which can lead to a decrease in soil productivity.

The widespread types of chemical degradation in soils are an excessive decrease or increase in pH (acidity or alkalinity), an increase in soluble salt content (salinity), a decrease in organic matter content, and a loss of mineral nutrients through leaching or crop offtake. Salinity and alkalinity are closely related and thus will be discussed together.

SOIL pH AND DEVELOPMENT OF SOIL ACIDITY

Chemically fertile soils typically have a pH range of 5.5–7.5. Soil pH is determined by the mineralogical makeup (such as clay minerals, various metal oxides and hydroxides, lime, etc.), organic matter content of the soils, and dissolved carbon dioxide in the aqueous phase. In spite of small diurnal or seasonal fluctuations, soil pH is strongly buffered by these factors. Any measure of pH below 7 is defined as the active acidity, whereas the ability of the soil to maintain a low pH level is referred to as the potential acidity. The active acidity represents the concentration of H^+ ions in the soil solution. Potential acidity includes exchange and non-exchangeable

(titratable) acidities. The exchange acidity includes the H^+ ions associated with the cation exchange sites on the clay mineral and organic fractions. The exchange acidity as a portion of total acidity varies with the mineral makeup of the soil and with the percentage base saturation. There is an equilibrium between active and exchange acidities, and as the H^+ ions in soil solution are neutralized, the cation exchange phase releases new H^+ ions into the solution. The sources of soil acidity are humus, aluminosilicates, hydrous oxides, and soluble salts.^[1]

Humus or humic matter causes acidity through dissociation of H^+ ions in its carboxylic, phenolic, and similar H^+ ions yielding functional groups. The humic fraction is considered as the weak acid component of the total acidity. The cation exchange sites on aluminosilicate clay minerals are occupied by various cations present in the solution phase. The portion of the total exchange sites occupied by H^+ ions increases as the portion of basic cations such as calcium (Ca), potassium (K), magnesium (Mg), and sodium (Na) are reduced through leaching or by plant uptake. This process is accompanied by a reduction in pH, as the dominating exchangeable H^+ ions controls the solution phase. When the soil pH falls below 5.5, aluminum (Al) in octahedral sheets dissociates and is adsorbed in an exchangeable form by clays, thereby increasing the Al saturation. Exchangeable Al is the major cause of exchange acidity. When dissociated from the exchange complex, these Al^{3+} ions produce H^+ ions through hydrolysis reactions. Hydrous oxides of Al and iron (Fe) either in free crystalline and amorphous forms or as coatings or interlayers in clay minerals are also subjected to stepwise hydrolysis and thus produce H^+ ions. The strongly adsorbed Al^{3+} ions on the exchange sites reduce the effective cation exchange capacity of the soil.^[1]

Soil acidity limits the plant growth by H^+ toxicity and decreases the macronutrient base cation content. Furthermore, the solubility of Fe, manganese, and Al containing minerals is enhanced at low pH levels, and the toxicity of these elements becomes a major problem. The activities of soil organisms, including nitrifying bacteria, are severely restricted at pH levels lower than 5.5.^[2]

Soluble salts stemming from dissolution of soil minerals or from fertilizers may directly or indirectly cause acidity. When only the cation of a salt is taken up by plants, H^+ ions released from roots can contribute acidity. Human activities may accelerate or initiate acidification of soils. Fertilizers, especially those of ammonium, indirectly cause acidity by producing H^+ ions as a by-product of nitrification. A monoculture with an excessive use of fertilizers on sensitive soils often results in the depletion of bases and an increase in soil acidity. Soil acidification can also arise as a result of changes in land use pattern, mostly owing to differential rooting patterns and nutrient requirements of plants. For example, establishment of coniferous forest on former grassland in New Zealand increased exchangeable acidity in the top 20–30 cm of soil.^[3] Oxides of nitrogen and sulfur released in the atmosphere by industrial activity are washed onto soils with rainfall (acid rains). Acid rains are not confined to industrial areas but are transported for long distances by mass air movements and affect both agricultural areas and forestland. Forests are especially vulnerable to atmospheric deposition of acids.^[4]

SALINITY AND ALKALINITY

Salinity

Salinity is a common problem in arid and semiarid regions where evapotranspiration exceeds rainfall (dry land salinity). Under these conditions (salinization regime), there is not enough water to wash the soluble salts down the profile below the rooting zone. Thus, soluble salts, originating from various sources, accumulate in the soil profile at certain depths—known as the salic horizon—or at the soil surface (Fig. 1), depending on the water regime. The potential for soil salinization may be greater in irrigated agricultural areas because even good quality irrigation water contains appreciable amounts of salts. If not washed from the soil profile to a drainage system by the leaching fraction of water, the concentration of chloride, sulfate, carbonate, and bicarbonate salts of Na may increase in the soil profile in a very short period (irrigation salinity). Another cause of salinity is the absence of a drainage system or poor drainage, especially in lowlands.^[5] Land use changes may induce or accelerate soil salinization. For example, clearing of perennial species and converting the land to production of annual crop species with much lower transpiration rates have led to rising water tables across vast areas of Australia. Consequently, the upward capillary movement of water carried the dissolved salts, previously present at depth, to the rooting zone.^[5,6] The sources of soluble salts, besides irrigation water, are mineral weathering, fertilizers, salts used on frozen roads, atmospheric transfer of sea spray, and lateral movement of groundwater from salt-containing areas. The contribution from each of these sources depends on the geographical position and topography of the area. In this respect, coastal areas,

Fig. 1 Salt crusts on soil surface caused by irrigation with low quality water in Faisalabad, Pakistan.

Source: Photo courtesy of Dr. C. Kirda, University of Çukurova, Turkey.

especially delta plains and regions lacking natural water outlets, are the most vulnerable areas. It is a well-established fact that unless the salts are properly discharged to the sea by an effective drainage system, the salinity problem cannot be eliminated but will only be transferred to another location.

Salinity affects plant growth by affecting water and nutrient uptake and through specific toxicity of Na, chlorine (Cl), and boron. The dissolved salts in water increase the osmotic potential, thereby creating the so-called physiological drought. Toxicity develops when the ions taken up from soil solution accumulate in leaves. As water is lost in transpiration, the concentration of the toxic ions increases and causes damage to various degrees, depending on the sensitivity of plants. Salinity affects the mineral nutrition of plants by reducing the availability and uptake of nutrients through the interaction of Na and Cl with nutrient cations and anions and by interfering with the transport of elements within the plant.^[7]

The degree of salinity is measured as electrical conductivity of a soil saturation paste or extract and is reported as deci Siemens per meter (dS/m). Plant sensitivity to salinity is expressed as a percent decrease in yield at a given level of salinity.

Alkalinity

Addition of salts to soils increases the concentration of Na in the soil solution more than those of Ca and Mg and alters the

composition of the exchange phase in favor of Na, because the Na salts are the most soluble salts in nature. This increase in exchangeable Na (Na_x) is called sodication, and soils degraded in this manner are referred to as sodic soils. The measure of sodicity is exchangeable sodium percentage, which is the ratio of Na_x to cation exchange capacity. This parameter is sometimes expressed as the exchangeable sodium ratio, which is the ratio of Na_x to other exchangeable cations. If the soil solution contains CO_3^{2-} and HCO_3^- in excess of Ca^{2+} and Mg^{2+} , highly soluble Na salts of these anions hydrolyze and the soil pH rises above 8.5. This process is termed as alkalization. Sodic soils do not necessarily have high pH, but in well-aerated soils, alkalization often follows sodicity. Sodicity, although a chemical property, has adverse effects on soil structure. As Na_x increases, the binding effects of divalent Ca and Mg ions on clay particles are overcome by the dispersing action of Na ions. Dispersed particles move with water and quickly clog the soil pores, causing drastic reductions in water and air permeability in sodic non-saline soils.^[2]

DEPLETION OF SOIL ORGANIC MATTER

The accumulation of soil organic matter, namely humus, in soils starts with the production of biomass and approaches equilibrium dependent on the effects of factors such as climate, type of vegetation, topography, soil texture, and drainage conditions. At equilibrium, when additions by biomass and removal by mineralization are in balance, organic matter contents range from less than 1% in arid regions to over 20% in organic deposits of cool humid climates. Any change in these factors may disturb the system, and a new equilibrium toward depletion of soil organic matter results. A highly disturbing factor in this respect is cultivation. Less organic material is returned to soil at harvest in most cropping systems, and tillage accelerates decomposition of soil organic matter.^[3,8,9] Man-made changes in plant cover, such as the conversion of forests and grasslands to croplands, promote rapid decomposition of the organic matter present in soils.^[8,9] Soil erosion is another factor that causes significant reductions in soil organic matter content, first, by decreasing the overall productivity and thus the production of biomass, some of which is returned to soil, and second, by carrying away the organic matter present in the lighter fraction of the surface soils.^[8]

LOSS OF PLANT NUTRIENTS

Plant nutrient elements are continuously lost from soils by crop removal (nutrient mining), erosion, leaching, and volatilization at rates determined by the type of vegetative cover, cropping system, and climatic conditions. In natural systems such as grasslands and forests, nutrient losses from soils are somewhat compensated by returns from falling plant debris and mineral weathering. On the other hand,

in intensive agriculture, much larger amounts of nutrients are taken away from soil with little return in crop residues, in many cases, exhausting the nutrient reserves in soils.^[1] Erosion permanently removes the readily available nutrients from the topsoil, which is the most productive layer.

Leaching losses in agricultural lands can be significant for anionic nutrients, especially for nitrate, under various farming systems.^[10] Basic nutrient cations such as Ca, Mg, and K may be leached from soils acidified by atmospheric deposition^[11] or from those under shifting cultivation.^[12]

CONCLUSION

Soil chemical degradation can be started and/or accelerated by improper use. Therefore, care should be taken to consider the climatological factors and quality of all agricultural inputs, including that of irrigation water, in the management of soils.

Degradation: Critical Limits and Irreversible Degradation

Anthony R. Dexter

Institute of Soil Science and Plant Cultivation (IUNG), Pulawy, Poland

Michael A. Zebisch

German Agency for International Cooperation, Tashkent, Uzbekistan

Abstract

The major causes of soil degradation are compaction, loss of organic matter, salinization, and pollution. Soil properties that are important for crop growth or for soil management must often lie within certain critical limits. Degradation of topsoils is usually reversible, whereas degradation of subsoils is much more difficult to reverse or may even be permanent.

INTRODUCTION

The major causes of soil degradation are compaction, loss of organic matter, salinization, and pollution. Soil properties that are important for crop growth or for soil management must often lie within certain critical limits which are summarized in Table 1. Degradation of topsoils is usually reversible, whereas degradation of subsoils is much more difficult to reverse or may even be permanent.

SOIL STRUCTURE

Virgin soils have structures that took hundreds or thousands of years to form as a result of pedogenic processes. When such soils are brought under cultivation, some structural features are destroyed permanently. However, if the soil is managed carefully and appropriately, then it can be productive and can form part of a sustainable ecosystem. Soil with a good structure has a wide distribution of pore sizes, and the structure is stable.^[1] A wide distribution of pore sizes is necessary for soil function and arises when the soil primary particles are arranged into compound particles of different sizes. The structure will be stable if the clay and other colloidal particles, which glue the soil together, remain flocculated and do not disperse when in contact with water. Therefore, a low value of clay dispersibility is required for a stable soil structure. Factors associated with low clay dispersibility include organic matter and calcium. Factors that cause clay dispersion include the presence of sodium and mechanical energy inputs, e.g., from excessive tillage, especially when the soil is wetter than the lower plastic (or lower Atterberg) limit.^[2]

Soil Bulk Density

The bulk density of the soil (or mass per unit volume) is not important as such. Plant roots, for example, do not sense

soil density. What they do sense is mechanical impedance to elongation, which is positively correlated with bulk density, although the correlation is different for different soils. Effects of bulk density on root growth for soils of different clay contents are shown in Fig. 1. The values in this figure are indicative only because mechanical impedance depends on soil water potential, clay mineralogy, soil physical chemistry, and other factors. Roots may also bypass the dense parts of a soil by growing in cracks and biopores. Therefore, an exact relationship between bulk density and root growth is not to be expected. Bulk density is often used as an indicator of the soil physical condition, although it is not a measure of soil function and its use is subject to limitations.

HYDRAULIC PROPERTIES

Water Retention

Soil must be able to store useful amounts of water for crop growth. The maximum amount that can be held is known as the *field capacity*, which is the water content of a soil after at least 2 days of drainage following heavy rain or a large irrigation. In the laboratory, it may be measured as the water content of soil samples when drained from saturation to a matric water potential of -100 h Pa. The dry limit for crop use is the *permanent wilting point*, which is a plant characteristic. This is the water content of the soil below which plants lose turgor pressure and cease growing, even under conditions of zero transpiration. For many crops (e.g., cereals), it corresponds to a matric water potential of -1.5 MPa. The *available water capacity* or *plant available water* is defined as the difference between field capacity and permanent wilting point, and quantify how much water a soil can store for use by crops. The higher this quantity, the better. However, the soil must be aerobic at field capacity. Soil compaction reduces the

Table 1 Critical limits and optimum values of soil properties for most soils under typical agricultural use.

	Soil water/solution			Aeration			Mechanical	
	Matric potential (kPa)	EC (mS cm ⁻¹)	Acidity (pH)	Air-filled porosity (%)	Redox potential Eh (mV)	ODR (μg m ⁻² s ⁻¹)	Penetrometer resistance (kPa)	Friability
Maximum	-5 to -10 ^a	1.5–12 ^b	7.5 ^b	—	700	—	2000	—
Optimum	-20	<0.5	7.0	15	450	>50	1000	0.4, ^c 0.8 ^d
Minimum	-1000 to -1500 ^b	—	6.5 ^b	10	330	20–30 ^b	500	0.2, ^c 0.4 ^d

value of the available water capacity and also the air-filled porosity through preferential destruction of the larger pores.

Infiltration and Hydraulic Conductivity

Rain or irrigation water must infiltrate into soil where it can be stored for subsequent use by crops, otherwise, runoff will occur with adverse consequences (e.g., erosion, flooding, transport of nutrients, etc.). Infiltration occurs in two main stages. At short times, infiltration is rapid because water is being “sucked” into the soil by capillary forces. At longer times, infiltration reaches a steady rate equal to the saturated hydraulic conductivity of the soil. Whereas irrigation rates can be reduced to match the ability of the soil to absorb water, no such control over rainfall is possible. To avoid runoff, the rate at which the soil can absorb water should be greater than

the highest rainfall rates that may be expected. Because of the two-stage nature of water infiltration, the onset of runoff depends not only on rainfall intensity but also on storm duration and “storm profile” (how intensity varies with time through a storm). Subsoil compaction may reduce hydraulic conductivity by factors of 10 or even 100. Therefore, once the pore space in the topsoil has been filled-up with water, runoff may occur even at low rainfall rates.

SOIL AERATION

Air-Filled Porosity

Adequate soil aeration requires a network of continuous air-filled pores throughout the soil volume. For soil to be aerobic at field capacity (see earlier), these pores need to be larger than 30 μm. Air-filled porosity is the simplest measure of soil aeration.^[4,5] The soil air should contain at least 5% oxygen.

Electrochemical Measurements

Redox potential, E_h , may be measured by the electrical potential between a saturated calomel reference electrode and a platinum (Pt) electrode.^[4] E_h ranges from +700 mV in fully aerobic conditions to -200 mV in completely anaerobic and reduced conditions. A value of E_h = +300 mV corresponds to the initiation of iron reduction, which causes the blue mottling that is characteristic of inadequately aerated soils.

The oxygen diffusion rate (ODR) is a measure of the rate at which oxygen molecules impact with a simulated root that is inserted into the soil. Typically, a root is simulated by a Pt wire of 0.5 mm diameter at an electrical potential of -650 mV relative to a saturated calomel reference electrode.^[4] When an oxygen molecule impacts with the electrode, it is reduced and four electrons flow in an electrical circuit. The electrical current in the circuit is proportional to the number of molecules per second which impact with the Pt wire electrode.

SOIL STRENGTH

Penetrometer Resistance

Penetrometers are used to measure soil strength in the field.^[6] Penetrometer resistance is measured by the force required to push a conical metal probe into the soil. The probe is typically of about 20 mm in diameter (or smaller in strong soils) and 30° total included angle. Penetrometer resistance is expressed as the force per unit projected area of the cone, in kPa or MPa. When penetrometer resistance >5 MPa, crop development is seriously affected. Penetrometer resistance increases sharply with decreasing soil water content.

Tillage becomes difficult when penetrometer resistance >2 MPa. There is no real upper limit of soil strength for tillage; it is a question of how much energy the farmer is prepared to use to produce the desired soil structure.

The lower limit for soil strength arises from the requirement for the soil to support traffic and from the need for the soil to be strong enough to prevent plants from falling over. It has been found that passage of a tractor across the soil was not possible when penetrometer resistance was <250 kPa, was possible when it was in the range 250–500 kPa, and was easy when it was >500 kPa.^[7] Trafficability of soil depends very much on the design of the vehicle. Similarly, the ability of the soil to hold plants upright depends not only on the soil but also on the geometry and mechanical properties of the plants.

Precompaction Stress

When soil is subjected to compressive stresses, it may compact (i.e., its volume will reduce) until the stress required for further compaction is equal to the applied stress.^[8] Compaction is an irreversible deformation, and the soil will not return to its original volume when the applied stress is removed. Further compaction will not occur until the previous maximum value of applied stress or *precompaction stress* of the soil is exceeded. Precompaction stress can be measured in the laboratory, and can then be used to determine the vehicle parameters (e.g., total weight, axle loads, and tire inflation pressures), which may be used without causing further compaction damage. It is not possible to give a maximum value for precompaction stress, as each case needs to be considered separately. For example, some soils even after light traffic may have extremely low hydraulic conductivities or infiltration rates which would then give rise to water runoff. For every soil, there is a critical value of precompaction stress which should not be exceeded and which must be determined in relation to all aspects of soil function.^[8]

Friability

Friability describes the ease with which soil can be tilled to produce a seedbed. This can be evaluated qualitatively

in the field by feeling how easily the soil crumbles when rubbed between the fingers. Friability depends on the existence of air-filled pores that provide surfaces of weakness along which the soil can break readily. Such pores are typically microcracks that are wider than 30 µm and therefore air-filled at field capacity. Friability can be quantified either from the decrease of tensile strength with increasing sample size or from the coefficient of variation (standard deviation divided by the mean) of tensile strength values.^[9] A well-structured soil has a high friability, whereas a structureless soil has a small (in the extreme case, zero) friability. Friability is greater when the content of readily dispersible clay in the soil is smaller; in non-compacted soil relative to compacted soil, and in direct-drilled (zero-tilled) soil relative to conventional (plow) tilled soil.

SALINITY AND SODICITY

The term salinity refers to the amount of salt (usually sodium chloride) in the soil, whereas sodicity refers to the amount of sodium adsorbed on the surfaces of the soil particles (most of the surface area exists on the clay particles). Increase of salinity or of other sodium salts (e.g., sodium carbonate and sodium bicarbonate) produces an increase of sodicity. Salinity of soil water is usually measured by electrical conductivity, EC, and sodicity is usually expressed as the exchangeable sodium percentage, ESP.

Salinization of soil occurs when the input of salt is greater than the output. This can occur in irrigation systems where there is some salt in the irrigation water and where there is inadequate drainage to remove these salts. It can also occur as dryland salinization in which clearance of natural deep-rooted vegetation and its replacement by crop or pasture species reduces water extraction from deep layers. The water table can then rise and can bring salt of geological origin toward or to the soil surface.

Sodicity causes soil particles to repel and to disperse in water. Therefore, sodic soils are highly unstable. They dry into extremely dense, strong blocks and their friability is essentially zero. Tillage of such soils, if possible at all, can be done only over a very narrow range of water contents. Sodic soils may exhibit a complete loss of soil function. The critical value of ESP beyond which soil physical degradation becomes apparent is 15%.

ACIDITY (PH)

The normal range of soil pH values is from 4 to 10. However, most plants prefer conditions between pH 6.5 and 7.5. Some specialized plants tolerate values outside this range. In highly acidic conditions (pH < 5), some heavy metals and other elements such as iron, copper, zinc, cobalt, and aluminum become soluble and can become toxic to plants and may be mobilized in the environment with the potential

to cause pollution. In agriculture, there is a natural tendency for pH values to drop. A typical rate of decrease of pH might be 0.4 unit for every 10 years although, of course, this depends on the soil type and on conditions. Therefore, soil pH must be adjusted periodically by additions of lime (as calcium hydroxide or calcium carbonate).

DEGRADATION: REVERSIBLE OR IRREVERSIBLE?

All types of soil degradation can be caused very easily. However, a cure may be either very slow and expensive or completely impracticable.

Symptoms of degradation of the topsoil (i.e., the arable layer in agricultural soils) include slumping, crusting, low friability, and so on. These problems can usually be alleviated by increasing the soil organic matter content and by adding calcium compounds such as gypsum (calcium sulfate) or lime if the soil is acidic. Organic matter can be increased by changing crop rotations to include a pasture phase, by keeping plant cover all the year round, by adding manures, and also by minimizing losses of soil organic matter, which can occur as a result of excessive or high-intensity tillage. Organic matter increases soil aggregation and reduces clay dispersion in water. Calcium compounds flocculate the clay, thereby reducing dispersion and increasing soil stability. Clay floccules form the building blocks for larger compound particles such as aggregates. The use of such practices over a number of years can produce a soil structure that is better for agricultural production and is more stable. Compaction damage of topsoils is usually not permanent because of the ameliorative effects of tillage, biological activity, and wetting and drying cycles.

Degradation of the subsoil often occurs through compaction.^[8] Subsoil tillage may make a temporary improvement, but often the soil will recompact to be as bad as or worse than it was before subsoiling. However, recompaction can be minimized if vehicle weights or axle loads after subsoiling are kept significantly below those that caused the original compaction. Any attempt at subsoil tillage should be done only when the whole soil layer to be tilled is drier than the plastic (lower Atterberg) limit; otherwise, the soil will be destabilized. In many soils, the effects can be considered to be permanent.

Soil salinity can be cured in principle by leaching. However, dryland salinity usually cannot be reversed but may be slowed or halted by the planting of deep-rooted plants (e.g., salt-tolerant trees) that can transpire enough water to stop further water table rise. Sodicty can be cured by displacing the sodium with calcium. However, this is difficult because sodic soils have an extremely low permeability to water.

Displacement and leaching may be accelerated by not using pure water but using water with a high enough electrolyte concentration to keep the clay flocculated and hence the permeability high.^[10,11] It is necessary to consider where the displaced sodium will go in order to avoid degradation of other areas or pollution of water courses.

Heavy metals can be removed slowly from topsoils by “hyperaccumulator plants,” which can be harvested and taken to a safe place for disposal. However, heavy metals are often best controlled by keeping them “fixed” in the soil (adsorbed on the exchange complex). This may require liming of the soil periodically for all time, otherwise the naturally occurring pH drop of the soil may eventually mobilize the heavy metals in the environment. This is the so-called “chemical time bomb” effect.

Degradation: Economic Incentives and Investments

Dennis Wichelns

International Water Management Unit, Colombo, Sri Lanka

Abstract

Soil degradation reduces the productivity of soil and water resources in many areas of the world, causing reductions in crop yields, higher production costs, and lower net income from agriculture. Many researchers agree that soil degradation occurs, in part, because of inappropriate decisions regarding inputs and outputs in agriculture. Yet not all researchers agree on the size of economic damages that result from soil degradation. Researchers also disagree regarding the appropriate allocation of public funds between amelioration activities that reduce the rates of soil degradation directly and research that will generate knowledge of new production methods.

INTRODUCTION

Some authors describe the levels of soil degradation as serious, and they warn that worldwide food production will not keep pace with the increasing demand without substantial expenditures to reduce soil degradation.^[1,2] Others suggest that investments in research are needed to ensure that aggregate food production will be sufficient to meet future demands.^[3–5] Those authors also suggest that public expenditures on agricultural research will have greater impacts on efforts to produce food in the future than expenditures made explicitly to reduce soil degradation.

Both perspectives regarding soil degradation have merit. The economic impacts of soil degradation might be moderate when viewed from a global perspective, but the impacts are severe in selected areas.^[6] Policy reforms and public investments are needed in those areas to reduce soil degradation, improve rural incomes, and enhance food security.^[7] A combination of expenditures on amelioration and research is needed to achieve those goals. The authors examine the potential role of policy reforms and public investments in areas where soil degradation reduces agricultural productivity and household incomes, such as in Asia and sub-Saharan Africa.

CONCEPTUAL FRAMEWORK

Both the farm-level and off-farm impacts of soil degradation arise, in part, because of imperfections in the market structure in which households and firms operate. In most areas, land rental markets do not include provisions by which tenant farmers can gain the long-term benefits of investments in soil management programs. Hence, tenant farmers choose crops and inputs to maximize near-term net revenues, with insufficient consideration of long-term

impacts. Incentives to consider off-farm impacts also are absent in many production settings. Farmers and herders often can choose inputs to maximize net revenues, without considering the impacts of their decisions on other farmers and herders, or on environmental resources.

Market imperfections can be corrected with policy interventions that modify the prices or availability of inputs, or the prices of output generated by firms and households. Quantitative restrictions or per-unit taxes on polluting inputs will reduce the use of those inputs. Per-unit subsidies, low-interest loans, and cost-sharing programs will motivate greater use of inputs and technologies that generate less soil degradation per unit of output. Public investments in research and development also will lower the incremental cost to firms and households of implementing socially desirable production methods. The use of public funds for research and development can be viewed as an effort to address the market imperfection associated with public goods. All firms and households might benefit from new knowledge regarding production methods, but individual firms lack incentives to invest in discovering that knowledge.

In most countries, government policies influence farm-level decisions regarding production activities. Policies that do not reflect resource scarcity or the potential off-farm impacts of soil degradation contribute to the inappropriate use of inputs. Often, policies that are implemented to achieve desirable goals contribute unexpectedly to soil degradation. For example, some governments reduce the farm-level cost of water and energy to promote higher levels of aggregate crop production. The long-term impacts of such subsidies can include waterlogging, salinization, and groundwater depletion.

Macroeconomic policies also have unintended consequences on farm-level decisions. Government procurement programs, exchange rate policies, and credit availability

influence cropping patterns and the types of inputs used in production. Some governments require farmers to sell crops to public agencies at prices below market values. Procurement requirements can reduce farm-level incentives for applying irrigation water and fertilizer. Overvalued exchange rates also reduce farm-level incentives to use fertilizers by making export crops less attractive to potential buyers.

EMPIRICAL EXAMPLES

The impacts of policies on soil degradation are found in areas characterized by intensive agricultural production and where production is extensive, with little use of chemicals and other modern inputs.^[7] Policy reforms and public investments in research and development can reduce soil degradation in both areas. The authors describe recommendations for the Indo-Gangetic plains (an intensive area) and sub-Saharan Africa (an extensive area).

Intensive Agriculture in Asia

Government policies that reduce the farm-level cost of water, energy, and machinery have contributed to the intensification of agriculture in large portions of Asia.^[8–10] Farmers on the Indo-Gangetic plains were motivated to replace traditional wheat varieties with high-yielding varieties during the 1960s and 1970s. The new varieties required more irrigation water and fertilizer, and those inputs were provided to farmers at subsidized prices. The intensification of agriculture generated increasing yields of food crops throughout the 1980s.

The rate of increase in crop yields on the Indo-Gangetic plains slowed markedly in the 1990s, causing concern regarding future food production in the region.^[7,11–13] One cause of the declining growth rates is soil degradation. Large areas have become waterlogged and saline because of excessive irrigation. In some areas, groundwater volume and quality are threatened by the widespread use of tube wells by farmers who receive electricity at heavily subsidized prices.^[14] The inappropriate use of fertilizers also contributes to the declining rates of growth in crop yields.^[15] In some areas, farmers lack the funds or information needed to apply the correct combinations of nutrients.

Appropriate policy reforms include adjusting the prices of irrigation water, electricity, and fertilizers to reflect production costs and scarcity values. In areas where volumetric pricing is not feasible, allocation policies can motivate farmers to improve resource use efficiency. Public investments in research regarding soil, water, and nutrient interactions can generate information describing how these inputs can be used to maximize net revenues, while minimizing the farm-level and off-farm impacts of soil degradation. Research also is needed to determine the optimal

program for improving resource use, increasing household incomes, and enhancing food security in rural areas.

Extensive Agriculture in Sub-Saharan Africa

Food production per capita has declined in sub-Saharan Africa, as population has increased faster than agricultural production.^[16] The causes of slow growth in agricultural productivity include poor soil fertility, insufficient use of chemical and organic fertilizers, and inadequate investment in irrigation systems and other infrastructure.^[17,18] Water scarcity and the inadequate use of fertilizers have resulted in soil degradation in many areas. In addition, government policies that have taxed agriculture heavily have limited the farm-level accumulation of capital and discouraged farmers from making the investments needed to enhance soil productivity.

Appropriate policy reforms include allowing farmers to receive full market prices for their output and removing import restrictions on fertilizer. Incentives that motivate private firms to import, distribute, and deliver fertilizers to farms also will motivate greater use. Public investments in rural infrastructure, such as roads, warehouses, and distribution centers, will stimulate greater use of fertilizer, while also enhancing farm-level crop marketing opportunities. Research designed to determine optimal water and fertilizer management strategies in rain-fed areas also will be helpful in reducing soil degradation and improving rural incomes.

CONCLUSION

The economic impacts of soil degradation are severe in selected areas where reductions in soil productivity limit production opportunities and reduce rural incomes. Policy reforms and public investments are needed to reduce soil degradation and restore soil productivity in those areas. Knowledge gained from those interventions will be helpful in assessing the potential gains from additional investments in other areas where the impacts of soil degradation are less severe.

Degradation: Farm-Level Economic Implications

Dennis Wichelns

International Water Management Unit, Colombo, Sri Lanka

Ellen Burnes

MWH Americas, Inc., Sacramento, California, U.S.A.

Abstract

The role of soil and its interaction with other inputs can be described using conceptual and empirical production functions, although precise measures of the impacts of soil characteristics on crop yields are not always available. An optimization model is helpful in describing why degradation occurs and in identifying policies that might reduce the extent and severity of soil degradation. We present an economic model of farm-level agricultural production, which we use to examine farm-level decisions that lead to soil degradation and to describe policies that might be helpful in reducing soil degradation.

INTRODUCTION

Soil degradation has been defined as a reduction in soil quality, in response to natural or anthropogenic causes, in a manner that reduces current or potential productivity.^[1–4] The economic implications of degradation are described best by focusing on productivity, rather than on soil quality, which is difficult to quantify and does not account for the interaction of soil characteristics with other inputs, such as labor, capital, and management.^[5] Economists view soil degradation as a reduction in the productivity of soil, for a given set of inputs. As soil productivity declines, more units of other inputs are required to maintain the yield of crop or livestock products, and greater expenditures are required to achieve agricultural objectives.^[6]

A FARM-LEVEL OPTIMIZATION MODEL

An intertemporal optimization model is appropriate because of the following reasons: 1) farmers seek to maximize the present value of the sum of net revenues earned over time; and 2) soil is a durable resource. Production decisions in any year can affect soil productivity in ways that influence crop and livestock choices, input use, and yields in many subsequent years. If the rate of change in soil productivity is small, farmers might not be aware of the relationship between current decisions and long-term profitability. Consequently, they might not account for the cumulative, long-term impacts of soil degradation when choosing production strategies.

The objective function of the farm-level optimization model includes J crop and livestock activities and T time periods. Total revenue and total costs are functions of land, labor, capital, and other inputs:

$$\text{Maximize PVNR} \sum_{t=0}^T \sum_{j=1}^J [P_{jt} Y_{jt}(L_{jt}, B_{jt}, K_{jt}, A_{jt}) - TC_{jt}(L_{jt}, B_{jt}, K_{jt}, A_{jt})] [1 + r]^{-t}$$

where

PVNR is the present value sum of net revenue,
 P_{jt} is the price of crop or livestock product j in year t ,
 Y_{jt} represents the output of crop and livestock products,
 TC_{jt} represents the total costs of production,
 L_{jt} is the amount of land used in each production activity,
 B_{jt} is the amount of labor,
 K_{jt} is the amount of capital,
 A_{jt} represents all other inputs, and
 r is the appropriate discount rate.

We use this framework to analyze the farm-level impacts of reductions in soil productivity on crop yields, input use, and production costs. Our goals are to gain insight regarding why degradation occurs and to identify public policies for reducing the extent and rate of soil degradation.

FARM-LEVEL IMPLICATIONS

The opportunity to generate net revenue motivates farmers to maintain or enhance soil productivity. Key parameters in farm-level decisions include the prices of inputs and outputs and the available technology. The role of soil productivity is implicit in the technology of production, as described by the yield and total cost functions, Y_{jt} and TC_{jt} . Production functions describe how inputs are combined to generate output, whereas cost functions describe the expenditures required to produce a given level of output. Both production and cost functions represent existing technology, which determines how much output can be produced

Fig. 1 The impact of soil degradation on the labor required to maintain crop yield.

with a given set of inputs and what the cost will be to generate a desired amount of output.

The production and cost functions are described using subscripts for the crop or livestock activity, j , and the time period, t . The inclusion of the time subscript allows for changes or shifts in the functions over time, due to changes in the productivity of soil and other inputs. If soil productivity declines, greater amounts of labor, fertilizer, or other inputs will be required to achieve the same level of yield that once was obtained with fewer inputs. Hence, a larger expenditure will be required to achieve a given level of output.

A decline in soil productivity causes a downward shift in a crop production function if there are no changes in technology. Fig. 1 depicts a 2-D, conceptual relationship between labor and crop yield. If soil degradation causes the production function to shift downward over time, from Y_{11} to Y_{12} , the labor required to achieve the original yield, Y_A , will increase from L_A to L_B . If labor is not increased, the yield will fall from Y_A to Y_C .

Fig. 2 The impact of soil degradation on the cost of maintaining crop yield.

This effect can be described alternatively using total cost functions (Fig. 2). If soil degradation causes the cost function to shift upward from TC_{11} to TC_{12} , the cost of maintaining production at Y_A will increase from TC_A to TC_B . If expenditures for inputs are not increased, output will decline from Y_A to Y_C .

The value of net revenue will decline with soil degradation, if output is reduced while using the same level of inputs or if inputs are increased to maintain the original level of output. The optimal response to soil degradation likely will involve both a reduction in output and an increase in the use of some inputs. Farmers lacking knowledge, capital, or access to key inputs might be unable to respond optimally to soil degradation. Those farmers will sustain larger reductions in net revenue.

Optimal farm-level strategies regarding soil management and the prevention of soil degradation can be determined by evaluating the potential long-term impacts of decisions regarding production activities and input use. Several conditions are required to ensure that long-term impacts are considered when choosing near-term production strategies. Farmers must 1) understand the potential impacts of their decisions on soil productivity; 2) perceive that they will gain the future benefits of efforts to maintain or enhance soil productivity; and 3) have the financial ability or access to credit required to invest in measures that will generate returns primarily in future.

Farmers often have limited information regarding the impacts of their decisions on soil productivity. The shifts in production and cost functions that result from declining productivity can occur very slowly, such that farmers are not aware of an accumulating problem of soil degradation. In addition, the annual variation in crop yields and input requirements caused by weather events, pest infestations, and other stochastic influences can make it difficult for farmers to observe a downward trend in average productivity because of soil degradation. Public efforts to provide farmers with better information regarding the long-term impacts of production strategies can motivate them to implement optimal soil management programs.

Owners of land have an economic incentive to consider the long-term impacts of decisions because they will retain the incremental benefits generated by their actions. Tenant farmers and users of resources for which secure, long-term property rights are not assigned will lack that incentive in most cases. Incentives for tenant farmers can be provided by including requirements pertaining to soil management practices in their lease agreements and by writing those agreements for long periods.

Many farmers, particularly in developing countries, lack the financial ability or the access to credit required for implementing an optimal soil management program.^[7]

Private owners of farmland might perceive the economic rationale for investing in a subsurface drainage system to prevent salinization or constructing terraces to reduce erosion, but they might not have the funds required to make those investments. Public policies that provide farmers with low-interest loans or cost-sharing opportunities for making desirable investments can motivate the wider implementation of optimal soil management programs.

CONCLUSION

Soil degradation can be described as an economic phenomenon that causes production functions to shift downward and cost functions to shift upward. Greater amounts of complementary inputs are required to maintain the yields of crop and livestock products when soil productivity is reduced because of degradation. An optimization model describes the role of land, labor, and other inputs in agricultural production. Soil degradation is more likely to occur when 1) farmers are not aware of gradual reductions in soil productivity; 2) property rights are neither secure nor well defined or when tenure is of limited duration; and 3) farmers do not have the financial ability to implement optimal soil management programs. Public policies that clarify and enforce the assignment of property rights to farmland and those that modify the prices of selected inputs can motivate farmers to consider the long-term impacts of soil degradation when choosing production strategies.

Degradation: Food Aid Needs in Low-Income Countries

Abstract

Global food production has grown faster than the world's population in the past years. As a result, enough food is available worldwide, so that countries with production shortfalls can import food as long as they have adequate financial resources. Yet, many poor countries and millions of poor people do not have a share in this abundance. They suffer from food insecurity and hunger, which are the conditions associated with low-quality resources and inadequate purchasing power. For these countries, demand for food aid is high and is likely to increase unless steps are taken to implement improved policies and raise productivity. Gains in domestic production will likely stem from improved yields that are, in part, dependent on soil quality.

INTRODUCTION

The Economic Research Service (ERS) estimates that almost 33%—roughly 800 million—of the developing world's population suffer from insufficient food intake.^[1] For 67 lower-income countries, the amount of food needed to provide nutritionally adequate diets was estimated to be 17.1 million tons in 2000 and will increase by 70% to more than 22 million tons by 2010. Sub-Saharan Africa is the most vulnerable region and is projected to account for almost 80% of this “nutritional” gap (of the 67 study countries) in 2010 (Table 1).

The donor countries have showed an interest in providing food assistance to low-income countries; however, there are budget pressures that limit these transfers. The question at hand is what are the factors that are leading to food insecurity in these countries and what kind of changes can be initiated to compensate for the decline in the quality of resources without reducing the benefits of increased productivity.

IMPROVING AGRICULTURAL PRODUCTIVITY

A common characteristic among the food-deficit countries is the large contribution of domestic food production to food consumption, with only a very small share of domestic consumption provided by imports. Agricultural products are also very important sources of foreign exchange earnings to support the growing import needs. Agricultural production growth depends on the availability and quality of

resources. In low-income, food-deficit countries, this means land and labor because of limited use of new technologies.

Constraints in Expanding Agricultural Areas

In many low-income countries, most increases in agricultural output have stemmed from area expansion (Fig. 1).^[2,3] In sub-Saharan Africa, area expansion accounted for more than 80% of the region's grain output growth between 1980 and 1999. This means that yield growth contributed to less than 20% of the growth. In Latin America, area expansion accounted for 68% of the growth in grain production. In Asia, however, the reverse was true; area expansion accounted for less than 5% of the growth in grain output. In other words, gains in yields contributed to nearly all of the growth experienced in the region's grain output.

The long-term prospects for acreage expansion are not bright because, in most countries, a large part of land that could be used for farming is unfit to cultivate without major investment. In Latin America and sub-Saharan Africa, continued expansion of cropland means converting rangeland and forestland to crop production, a process with high economic and environmental costs. According to the estimates of Food and Agriculture Organization, about half of the land that could be used to produce food in sub-Saharan Africa has poor quality soil.^[3] Sub-Saharan Africa has a vast and diverse land area, but the region faces a number of resource constraints (such as

Table 1 Food gaps by region.

	2000 (million tons)	2010 (million tons)
Sub-Saharan Africa	10.70	17.50
Latin America	0.63	0.99
Asia	1.70	3.63
Other	0.17	0.18
Total (67 countries)	13.20	22.30

lack of water) to sustainable agricultural growth.^[4] Some countries, such as Sudan and the Democratic Republic of the Congo, have vast areas of rain-fed land with crop potential, while other countries such as Kenya and Madagascar have already exhausted their high-potential land. Demographic changes are placing increased pressure on land in the region. More than 20% of all vegetative land is degraded because of human causes; however, water and wind erosion account for a majority of the affected hectares. Much of this degraded area is in the Sahel, Sudan, Ethiopia, Somalia, Kenya, and Southern Africa. Historically, farmers adjusted to resource constraints by following several years of planting with several fallow years. However, population pressures have reduced the practice of these sustainable agricultural techniques, leading to declines in land productivity.

Given the constraints to area expansion, changes were made in the assumptions for area growth relative to the base scenario for sub-Saharan Africa, Latin America, and Asia using the structural framework of the ERS food security model. For sub-Saharan Africa and Latin America, we cut the projected area growth rates used for the baseline scenario into half for each country in the two regions. In Asia, we assumed the area to remain constant during the entire projection period under the new scenario, as population pressures will intensify competition for land. In sub-Saharan Africa, production in the baseline scenario was projected to grow at a rate of 2.1% per year; under the reduced area growth scenario, this rate is projected to fall to 1.7%. As a result of the slower production growth,

Table 2 Food gaps under alternative scenarios.

	Baseline (million tons)	Reduced area growth
Sub-Saharan Africa	17.5	25.6
Latin America	1.0	1.6
Asia	3.6	4.7

the region’s nutritional food gap in 2010 jumps more than 40% to more than 25 million tons (Table 2). In Latin America, the decline in production growth is much less significant—from 2.3% to 2.2%. The impact is less in this region because gains in yields are expected to be a more significant contributor to production growth than area expansion. In sub-Saharan Africa, both area and yield were estimated to contribute almost evenly to production gains; therefore, a cut in area growth is going to have a greater impact. This small change in production growth will still have strong implications for the region’s nutrition gap that is projected to rise 40% under this new scenario. In Asia, production growth is projected to slow from 1.7% to 1.6% per year, when area is held constant. This slowdown translates into a 30% increase in the nutrition gap for 2010.

Limited Use of New Technologies

The only option to sustain production growth is by increasing yields. Within the developing world, average regional grain yields are the highest in North Africa and the lowest in sub-Saharan Africa. Yields are highly dependent on the use of improved inputs, particularly fertilizer use. However, yields do not increase commensurately with fertilizer use. A cross-country estimate for the developing countries showed that a 1% increase in fertilizer use results in only a 0.1–0.3% increase in yields.^[4,5] The principal factor that limits yield response to fertilizer use is the inadequate supply of water during the growing season. Although water availability varies considerably across regions, it has been a serious problem in many countries. According to a study by World Bank, the depletion and degradation of water resources have become major problems many low-income countries facing.^[5,6] Within 10 years, if population grows at projected rates, per capita water availability will decrease by an average of 20% in developing countries and by 34% in African countries. The agricultural sector consumes over half the annual freshwater withdrawals in most of the countries and could face greater competing demands from household and industrial uses in the future.

The sparse rainfall that characterizes much of sub-Saharan Africa affects response to and demand for fertilizer.^[7,8] Farmers are reluctant to risk fertilizer use until rain begins to fall because inadequate moisture will fail to dissolve the nutrients in fertilizer (especially nitrogen)

Fig. 1 Sources of grain production growth, 1980–1999.

Table 3 Land use and agricultural productivity.

	Irrigated land (% of crop land)	Arable land (ha per capita)	Fertilizer use (kg per hectare arable land)		Agricultural productivity (agr. value added per agr. worker (1995 dollars))	
	1995–1997	1995–1997	1979–1981	1996–1998	1979–1981	1996–1998
North Africa	13.2	0.24	91	117	1255	1982
Sub-Sahara Africa	4.2	0.25	12	10	244	128
Asia	36 ^a	0.14 ^a	54 ^b	135 ^b	521 ^a	618 ^a

^aRegional average without Afghanistan, North Korea, and Vietnam.^bRegional average without North Korea.^cRegional average without Bolivia.

and crops can “burn.” Irrigation can make the use of fertilizer profitable and can increase agricultural output. However, in sub-Saharan Africa, only 4.2% of arable land is irrigated (Table 3). This is low even when compared with other developing regions. In Latin America, 13% of arable land is irrigated, and 36% is irrigated in Asia.^[9] The world average is 19%. There is potential for expanding irrigated area in sub-Saharan Africa, but it is costly and requires investment. Increasing the use of fertilizer raises production costs. In many low-income countries, particularly those in sub-Saharan Africa and Latin America, almost all fertilizers are imported, and the lack of adequate foreign exchange constrains the availability.

CONCLUSION

Uneven distribution of the world’s resources means that the poor, low-resource countries are vulnerable to food insecurity. Sub-Saharan Africa, the most food-insecure region, faces the challenge of achieving the following multiple goals: meeting basic human needs, stabilizing population, encouraging economic development, and conserving natural resources for future growth. In most low-income, food-deficit countries, gains in production have been achieved because of area expansion. However, population pressures and poor farming practices that have contributed to soil erosion and nutrient-deficient soils have already pushed farmers to marginal lands. Therefore, the only option for sustainable production growth is to increase yields. So far, most countries in the region are unsuccessful in adopting new technologies to raise crop yields and increase productivity.

Degradation: Food Security and Poverty

Pierre Crosson

Senior Fellow and Resident Consultant, Resources for the Future, Frederick, Maryland, U.S.A.

Abstract

While soil degradation does not appear to be a serious threat to world food security, this does not mean that measures to protect the soil are unimportant. On the contrary, they are very important. Continued protection of the soil against the inroads of degradation is essential to maintaining and increasing the global capacity to produce food. Using that capacity to achieve global food security requires an increase in the incomes of the poor worldwide. If that is done on an adequate scale, the problem of global food insecurity will be solved.

INTRODUCTION

Food-insecure people are defined here as those who are considered undernourished by the Food and Agriculture Organization (FAO) of the United Nations. These are people who do not consume enough calories over the course of a year to maintain normal body weight and support light physical activity. According to the FAO, there were approximately 780 million people who, by this definition, were food insecure in 1990.^[1] Almost all were from the less developed countries (LDCs) of Asia, Africa, and Latin America.

POVERTY AND FOOD SECURITY

The consensus among students of world agricultural development is that, where people are food insecure, it is mainly because of poverty. People are too poor to purchase the food needed for adequate nourishment. This means that the food-insecurity problem lies primarily on the demand side of world food markets. Soil degradation reduces the capacity of the land to produce food, which means that soil degradation is on the supply side of world food markets. In principle, it could also be on the demand side because degradation-induced production losses reduce farmers' incomes, and thus their ability to buy food.

This implies that reducing soil degradation would help solve the problem of global food insecurity to the extent that degradation significantly reduces farm income. The investigation of information on soil degradation and its productivity consequences suggests, with some caveats, that the effect of soil degradation on farm income is not significant on a global scale.

FAO data on the number of undernourished people in developing countries show that the 780 million in this category (in 1990) represented 20% of the total population of these countries. This was a marked decline from the 36% of

the LDC population that was food insecure in the late 1960s. It must be noted, however, that this improvement occurred in only Asia and Latin America. In Africa, the number of food-insecure people increased over the 20-year period, both as a percentage of the population and in absolute number.

In the 1990s, per-capita food production and per-capita income increased in Asia and Latin America, so it is likely that the population percentage and the absolute amount of food-insecure people in those areas declined. In Africa, however, the trends in food production and per-capita income continued to be unfavorable in that time frame, suggesting that, in percentage and absolute number, food-insecure people increased further.

These numbers indicate that despite the relatively good performance in Asia and Latin America, the global community continues to confront a serious problem of food insecurity in the LDCs, especially in Africa.

The consensus mentioned previously that poverty is the main reason for food insecurity includes the view that if food-insecure people had sufficient income and the global food trading system were no less robust farmers worldwide could increase food production enough to meet the higher demand at prices only moderately higher than those prevailing. It also was mentioned that because soil degradation is a supply factor in agricultural production, reducing soil degradation would not significantly contribute toward world food security. However, this assertion cannot be accepted on its face; it must be investigated. Specifically, we must review estimates of the extent and productivity consequences of soil degradation worldwide.

SOIL DEGRADATION

It should be noted that most soil scientists and the general public have viewed soil degradation as a serious threat to agricultural production capacity. In 1928, Hugh Hammond

Bennett—regarded as the father of the soil conservation movement in the United States—and a colleague published *Soil Erosion: A National Menace*.^[2] In the United States, this view of erosion was widely shared and persists among many soil scientists and others. The same view was more expressed, with respect both to the United States, and the world as a whole, by Brown and Wolf,^[3] and Pimentel et al.^[4]

The view has held despite the lack of strong scientifically reliable information about the amounts and extent of soil erosion or its productivity impacts, not only in the United States but around the world. In the United States, it was not until the U.S. Soil Conservation Service (an agency of the Department of Agriculture) conducted a comprehensive nationwide survey in 1977 that such information became available. On a global scale, no such data existed, even as late as 1988. Nelson^[5] expressed the consensus after conducting a comprehensive literature review and described worldwide evidence regarding the rate, extent, and severity of soil degradation as “extraordinarily skimpy.” Other students of the problem came to the same conclusion as well.^[6,7]

MEASUREMENTS OF SOIL DEGRADATION

In 1982, 1987, 1992, and 1997, the U.S. Soil Conservation Service (the Natural Resources Conservation Service) conducted nationwide surveys of erosion amounts comparable with those done in 1977. The surveys showed that over the period covered the amounts declined, both in total and per hectare.

In addition, studies done of the productivity consequences of erosion in the United States indicate that in the past they were, and in the future would continue to be, small. (In these studies, productivity is measured as crop output per hectare.) Crosson^[8] found that from 1950 to 1980, erosion in more than 600 counties in the Corn Belt and Great Plains reduced increases in corn and soybean yields by a cumulative 1.5–2%. That is, in 1980, yields of those crops were smaller by those percentages than they would have been without erosion. Crosson also found that erosion in those counties had no statistically significant effect on wheat yields.

Soil scientists at the University of Minnesota developed a Productivity Index model to estimate the future effects of soil erosion on crop yields. They applied the model to 39 million hectares of cropland in the Corn Belt and found that if 1977 rates of erosion were to continue for 100 years, corn yields at the end of the period would be approximately 4% less than without erosion.^[9]

In yet another study, a team of soil scientists, agronomists, and economists at the Department of Agriculture facility in Temple, Texas, developed the Erosion Productivity Impact Calculator, a model designed to estimate the effects of erosion on crop yields.^[10] The team used the

model to estimate the erosion-induced loss of yield in the nation as a whole that would occur if the 1982 crop production and management practices were to continue for 100 years. They found that at the end of that time period yields would be 2–3% lower than without erosion.

In a comprehensive review of 90 microscale studies of erosion-induced productivity losses in the United States and Canada, den Biggelaar et al.^[11] came to a conclusion consistent with that of the three previous studies.

Two studies done in the early 1990s provide the only reasonably reliable global scale estimates of the extent and severity of soil degradation on agricultural land. One of the studies, by a team headed by Roel Oldeman^[12] at the Agricultural University at Wageningen, the Netherlands, was based on a survey of more than 200 worldwide soil specialists. The specialists were asked to classify as degraded or not degraded the soils in their areas that were in permanent or annual crops, permanent pasture, or in forest and woodland. They were then asked to categorize each type of land into four degrees of degradation: light, moderate, strong, and extreme. To translate these estimates to the global scale, Oldeman et al. used FAO data showing that some 8735 million hectares were in the four land uses. Responses from the specialists were used to allocate these hectares into degraded or not degraded; if degraded, they were placed into each of the four degrees of degradation. The results showed that 1965 million of the 8735 million hectares (22%) were degraded. Of the 1965 degraded hectares, 33% were lightly so, 46% moderately, 20% strongly, and 1% severely.

Another global study of productivity effects of soil degradation was done by Dregne and Chou,^[13] specialists in dryland agriculture at Texas Tech University. They estimated the degradation-induced percentage losses of yield on irrigated cropland, rain-fed cropland, and range in dry regions of the world. (Dry regions are those in arid, semi-arid, and dry subhumid agroclimatic zones.) Using FAO data, Dregne and Chou found approximately 5100 million global hectares in the three categories of land use. Drawing on the published literature and other available evidence, as well as their experience in dryland agriculture, Dregne and Chou classified land in irrigated and rain-fed crop production into four categories by severity of degradation-induced losses of productivity. Slightly degraded land was estimated to have lost 0–10% of its undegraded level of productivity. The estimated loss for moderately degraded land was 10–25%, for severely degraded land the loss was 25–50%, and very severely degraded land was estimated to have lost more than 50%. For rangeland, the estimated losses of productivity in each of the four categories were assumed to be somewhat higher (e.g., slightly degraded rangeland was estimated to have lost 0–25% of its undegraded productivity). For each of the three land uses, Dregne and Chou divided the amount in each among the four degree-of-degradation categories.

Crosson^[14] used the data in the Dregne and Chou study to estimate that the weighted average cumulative global loss of soil productivity on the three classes of land use in dry areas was 12%. This is the loss over some period, which Dregne and Chou did not specify, but it must have been averaged over approximately three to four decades. Over three decades, the average annual rate of productivity loss would be 0.4%.

Crosson^[14] combined parts of the Dregne and Chou study with results of the Oldeman et al. study^[12] and calculated the global scale cumulative loss of productivity on land in all agroclimatic zones to be 5%. Oldeman et al. specifically note that their estimate is for the period from 1945 to 1990. Over that 45-year period, the average annual rate of loss would be 0.1%.

In the latter calculation, Crosson assumed that the degradation-induced loss of productivity on the undegraded land in the Oldeman et al. study (78% of the total land) was zero. With so much of the land in an undegraded state, the extent of degradation-induced losses of productivity on *all* the land necessarily would be small.

These results suggest that over the past several decades, the impact of soil degradation on United States and global agricultural productivity has been small. Results that estimate future erosion-induced losses of productivity in the United States suggest that with current rates of erosion, the losses would continue to be small.

CONCLUSION

The conclusion for both the United States and global scales is subject to five important caveats. First, other students of the United States and the global soil erosion issue do not agree with the conclusion;^[3,4] however, it must be noted that neither of these authors has directly confronted the argument made here.

Another caveat is that the data used in the Dregne and Chou and Oldeman et al. studies are subject to wide margins of error. Both sets of authors recognize this and warn against careless use of their data. If and when more reliable data become available, they may contradict these initial findings.

The third caveat, regarding global scale estimates, is that the estimates obscure the fact that in many areas, particularly in the LDCs, there are "hot spots" where soil degradation has been severe—with significant impact on the food security of people in those areas.^[15] In parts of sub-Saharan Africa, e.g., the productivity effects of soil degradation may be particularly severe on a local scale because of shallow depths of topsoil and a high concentration of nutrients in the surface soil layer. In these areas, the erosion-induced nutrient loss is particularly serious because supplies of inorganic fertilizers are either not available or are very expensive. Thus, to say that soil degradation on a global scale does not seem to be a

significant threat to food security does not mean the problem is not serious for the millions of people in particular locations affected by it.

Fourth, with respect to the global estimates, the estimates reflect experience over the past several decades. While soil degradation has not greatly reduced agricultural productivity over this period, this does not guarantee that, in the future, degradation could not increase enough to significantly threaten world food security.

Much will depend on whether land tenure systems in the LDCs move in the direction of providing farmers more secure property rights in the land. The evidence around the world is clear that where these rights are protected, farmers have incentive to invest in soil conservation because they can be confident that they will reap the gains of the investments. Several studies in Asia and Africa suggest that land tenure systems in those areas are slowly shifting toward more secure property rights in the land.^[16–18] If this trend continues, it will have much impact on the size of the future threat of soil degradation to world food security.

Finally, while soil degradation does not presently appear to be a serious threat to world food security, this does not mean that measures to protect the soil are unimportant. On the contrary, they are very important. For most farmers, land is by far their most important asset. The apparently low cumulative and present rates for erosion-induced losses of soil productivity are strong indirect evidence that farmers worldwide recognize this and have taken measures to protect their land against erosion damages. If this practice continues, soil degradation will not likely threaten future global food security.

Continued protection of the soil against the inroads of degradation is essential to maintaining and increasing the global capacity to produce food. Using that capacity to achieve global food security requires an increase in the incomes of the poor worldwide. If that is done on an adequate scale, the problem of global food insecurity will be solved.

Degradation: Greenhouse Effect

Eddy De Pauw

International Center for Agricultural Research in the Dry Areas (ICARDA), Aleppo, Syria

Michael A. Zoebis

German Agency for International Cooperation, Tashkent, Uzbekistan

Abstract

Soil degradation refers to a decline of soil quality that reduces the soil's productive capacity, sustainability, resistance to degradation, or the biodiversity of the supported natural ecosystems. Soil degradation is a global phenomenon, and its most important expressions are water and wind erosion, fertility decline, salinization, and waterlogging, or lowering of the groundwater table. Being both a cause and an effect of rural poverty, soil degradation is one of the most serious threats to the prosperity of rural populations worldwide and is accelerated by non-sustainable land management induced by rural poverty.

INTRODUCTION

The greenhouse effect refers to the trapping of heat in the lower levels of the atmosphere. The atmosphere allows a large percentage of the rays of visible light from the sun to reach the earth's surface and heat it. Part of this energy is reradiated by the earth's surface in the form of long-wave infrared radiation, much of which is absorbed in the atmosphere by water vapor and greenhouse gases, in particular carbon dioxide (CO₂), but also other trace gases, notably methane (CH₄), nitrous oxide (N₂O), and chlorofluorocarbons. This process of heat-trapping causes the earth's surface and lower atmospheric layers to warm to higher temperatures than would otherwise be the case. In fact, this natural greenhouse effect makes life on earth possible. Atmospheric concentrations of greenhouse gases have increased because of human activities, primarily the combustion of fossil fuels (coal, oil, and gas), deforestation, and agricultural practices. Since the beginning of the pre-industrial era around 1750, CO₂ has risen by nearly 30%, CH₄ by more than a factor of two, and N₂O by about 15%. Their concentrations are higher than at any time during the last 420,000 years. The human-induced greenhouse gas emissions are responsible for the rise of average global temperature of about 0.7°C over the last years, with the most rapid rise occurring since the mid-1970s. If the greenhouse gas emission trends continue, an increase in global mean surface temperature in the range of 1.5–6°C is expected by 2100^[1] (<http://www.ipcc.ch/press/sp-cop6.htm>). In addition, there is evidence that precipitation patterns are changing, sea level is increasing, glaciers are retreating worldwide, Arctic Sea ice is thinning, and the incidence of extreme weather events is increasing in some parts of the world.

The overwhelming majority of scientific experts, while recognizing that scientific uncertainties exist, believe

that global warming is at least partially linked to the increased concentration of greenhouse gases by human activities and that climate change is inevitable. This will have potentially major repercussions on water resources, agriculture, forestry, fisheries and human settlements, ecological systems, and human health with the developing countries being the most vulnerable^[1] (<http://www.ipcc.ch/press/sp-cop6.htm>).

LINKAGES BETWEEN CARBON, GREENHOUSE EFFECT, AND SOIL DEGRADATION

Soil degradation and the greenhouse effect are both linked to human activities and are likely to interact in the context of global climate change. The expected shift in climate patterns, which will involve changes in both temperature and rainfall patterns, has the potential either to accelerate degradational trends in regions where they already prevail or to initiate certain types of degradation in new areas where they do not exist. On the other hand, current or future soil degradation is likely to enhance the greenhouse effect through a reduced ability of the soil to retain carbon.

The global carbon cycle, showing the major reservoirs and flows of carbon in gigatonnes of carbon (GtC; 10¹² kg) per year, is outlined in Fig. 1. The main stores or “sinks” of carbon are the oceans, the lithosphere with geological deposits containing fossil fuels, the terrestrial ecosystems, composed of living biomass and soil, and the atmosphere. Of these, the oceanic carbon reservoir is the largest but least reactive, and the atmospheric reservoir, although the smallest, is the most critical one since it drives global warming. With the exception of the fossil fuel reservoir, each reservoir at times behaves as either a source or a sink of carbon, and it is the rate of exchange of carbon between different

Fig. 1 The global carbon cycle in about 1980.

Source: From Rosenzweig & Hillel.^[2]

reservoirs that determines whether they act as net sinks or sources of carbon. Fig. 1 represents an estimate and refers to the situation of fossil fuel use in about 1980. An estimate of carbon flows and reservoir sizes around 1995, based on the data provided by the Intergovernmental Panel on Climate Change (IPCC), is given in Table 1 and compared with the estimates of 1980.

Table 1 shows that the terrestrial ecosystems have both an important carbon source and sink role. They act as a source of atmospheric carbon through land use change and tropical deforestation, at the same time they act as an important sink through the regrowth of forests in temperate regions; 1.5–1.7 GtCyr⁻¹ is not accounted for. The “missing” carbon is probably going into the terrestrial biosphere in the northern hemisphere where it contributes to an increasing capture of carbon in terrestrial ecosystems through the CO₂ fertilization effect.^[3]

Within the terrestrial ecosystems, soils constitute the largest reservoir of carbon, which is retained in the form of soil organic matter. All soil types of the world have an

inherent capacity to store organic carbon, which is determined by soil temperature and moisture regime, internal drainage, textural composition, and clay mineralogy. World soils show great variation in soil organic matter content, with values of 4–6% (weight basis) in the most fertile to less than 0.5% in others.^[5]

Fig. 1 shows that soils are a net source of carbon to the atmosphere. This is attributed to the massive land use change resulting from the conversion of forests and other natural ecosystems into farmland. From a terrestrial carbon balance model, Esser^[6] estimated for the period 1860–1980 the net decline of the carbon pool in plant biomass at 22 Gt and in the soil at 5 Gt. If an adjustment was made for increased carbon mineralization resulting from the global temperature increase, the loss of carbon in the soil reservoir would have increased to 12 Gt.

Apart from land use change, soil degradation has been considered a major contributing factor to the loss of soil carbon to the atmosphere and therefore to an increase in the greenhouse effect. The main reason is that soil degradation, through the processes of erosion, salinization, and fertility decline affects the productive capacity of land, and as a result, less carbon is returned to the soil. In fact, due to degradation many soils throughout the world do not achieve their potential carbon-carrying capacity. This is particularly the case in most arid and semiarid regions of the developing world, where overgrazing, fuel wood collection, and opportunity cropping have seriously depleted the limited stock of organic matter. The resulting erosion, soil structural degradation, and fertility loss have often all but prevented the reestablishment of the natural vegetation, and in order to regain the original productive capacity, expensive reclamation or conversion into protected lands is required in huge parts of the dry areas.

Also in the (sub)humid tropics, particularly in Africa, soil carbon stocks have been much depleted due to a

Table 1 Global carbon flux budget.

Carbon flows	1980	1995
Annual atmospheric increase of CO ₂	3.0	3.4
<i>Sources</i>		
Terrestrial ecosystems	1.8	2.7
Fossil fuels	5.2	6.4
<i>Sinks</i>		
Terrestrial ecosystems		2.0
Oceans	2.5	2.0
“Missing”	1.5	1.7

generally negative nutrient balance resulting from inadequate fertilizer use and reductions of fallow periods in shifting cultivation systems.

The scale of soil degradation worldwide is certainly sufficient to have impact on the global terrestrial carbon stocks. Oldeman et al.^[7] estimated that 38% of the agricultural land, 21% of the permanent pastures, and 18% of the forests and woodlands worldwide are affected by one form or another form of soil degradation. However, an accurate assessment of the contribution of soil degradation to the greenhouse effect is difficult because available inventories of the actual extent of different soil types, their carbon-carrying capacities in different ecoregions, the extent of various types of land degradation, and the carbon contents of degraded soils are inadequate.

In addition, some of the degradation observed does not necessarily lead to carbon loss. In the case of erosion, carbon is transported from one place to another without involving an increase in mineralization. There is also evidence from the geological past that an increased atmospheric CO₂, coupled with warmer than current temperatures, higher rainfall, and increased biological activity—the scenario predicted by global change—could lead to higher concentrations of reactive bicarbonate (HCO₃⁻) in soil solutions, producing more deeply weathered soil profiles rather than atmospheric carbon.^[8]

Global warming is also likely to increase the risk of soil degradation. In its assessment of regional vulnerability to climate change,^[9] the IPCC anticipates an increase of global mean precipitation and the frequency of intensive rainfall, entailing an increased risk of soil erosion by water and of soil acidification in humid areas. However, arid and semiarid regions in Southern and Northern Africa, Southern Europe, the Middle East, and parts of Latin America and Australia are expected to become even drier. Such areas would then become affected by more frequent drought and associated wind erosion, salinization, and carbon mineralization. Most regions of the world are expected to experience an increase in floods because of the projected increase in heavy precipitation events. Whereas the IPCC study outlines likely global trends and can be used for policy guidance at regional level, a quantified assessment of the impact of global warming at national or subnational level is highly speculative owing to major uncertainties about the geographical location and magnitude of the expected changes.

Whether the soil ultimately serves as a source or a sink of carbon very much depends on the way it is managed. Even agricultural land is capable of storing more carbon if appropriate land management practices are adopted and thus to reclaim some or all of the carbon lost in the transformation from natural ecosystems. In this respect, the potential to increase the carbon sink is particularly high in the dry areas, because their carbon content is far below their potential and the size of desertified and degraded lands worldwide, estimated at some 2 billion hectares.^[3] Soil management principles advocated to increase carbon

sequestration include the increase of the total and subsoil organic matter content, soil microaggregation, and soil biodiversity.^[10] Among the technological options proposed are conservation tillage practices, crop residue management, shelterbelts and windbreaks, intercropping, optimal crop rotations, winter cover crops, fertility improvement through green manuring, fallowing, precision farming, and improvement in the soil moisture regime through irrigation and salinity management.^[2,10]

Generally speaking, land use practices designed to prevent or remedy soil degradation will contribute to carbon sequestration. Given the high spatial variability of soils, which will persist under global warming, it is essential that the proposed principles are fine-tuned for specific soils and ecoregions, and the practices adapted to local conditions.

Degradation: Mapping by Normalized Difference Vegetation Index (NDVI)

Zhanquo Bai

World Soil Information, International Soil Reference and Information Centre (ISRIC), Wageningen, the Netherlands

David Dent

Center for Sustainability Studies, Lund University, Lund, Sweden

Abstract

The title of an article in *Advances in Space Science*, *The exciting and totally unexpected success of AVHRR in applications for which it was never intended*, published in 2001 says it all. The advanced, very high resolution radiometer carried by National Oceanic and Atmospheric Administration satellites is actually of low resolution, but its large field of vision and daily global coverage make it ideal for global monitoring. And, by chance, the ratio of red to near-infrared radiation [normalized difference vegetation index (NDVI)] measured using the radiometer is a good indicator of vegetation dynamics. The NDVI trends were used in 2008 for the first global assessment of land degradation to be based on consistent physical measurements. The results contradicted received wisdom and met with the usual public reaction to a new truth: “It’s not true”; then, “It’s against scripture.” The final accolade, “We knew it all along,” has been a long time in coming because NDVI can only be a proxy for land degradation and it is hard to confirm in the field. But no one has come up with an alternative. More sensors, e.g., the Moderate Resolution Imaging Spectroradiometer operating since the year of 2000, yield more detailed, more direct measures of net primary productivity but cannot match the 30 years of NDVI data that reveal significant changes in the trends of land degradation.

INTRODUCTION

The land provides 95% of our food and clothing as well as timber, biofuel, freshwater, and environmental services that underpin our economy and society, and it is taken for granted. Between 1965 and 1980, the *green revolution* increased crop yields threefold; for a generation, global food production outpaced population growth, and political attention turned elsewhere. But the end of the era of cheap food and fuel has concentrated minds, again, on food security. So, policy makers face all the old challenges writ large:

- *Burgeoning demand:* By 2050, 70% additional food will be required than that at present, which is double in the developing countries.
- *We are not making any more land:* The area under cereals peaked in 1981, arable in 1991, while the period 1981–2011 has witnessed the degradation of one-quarter of the land surface, and tracts of the best land are being lost to urban development and infrastructure.
- *Food system is unsustainable:* The green revolution depended on cheap fuel, fertilizer, and irrigation applied to new, responsive crop varieties. Fuel and fertilizer are no longer cheap, water resources are overcommitted, and yields have leveled off—in some places, they are declining and there is compelling evidence that present land

use is driving land degradation, and climate change is leading to more extreme weather and a rising sea level that threatens prime farmland.

A U.K. All-Party Parliamentary Inquiry in 2010 predicted “a perfect storm” from the collision of ever-growing demand for food, energy, and freshwater; the stresses of climate change and land degradation; the destabilization of governments that cannot provide their people’s basic needs; and the migration from poor countries to those better endowed. And there are no charts, i.e., from 1981 to 2011, knowledge of the land and capacity to face land resource issues have atrophied.^[1]

Estimates of the extent and severity of land degradation, its costs, and its impact on food security and the environment are uncertain, so it has rarely been at the top of national policy agendas. The exception was the United States’ response to the Dust Bowl in the 1920s and 1930s; the United States continues to reap the benefits of that investment, but, in general, the investments required to arrest land degradation are not being made—they are not even known. Uncertainty stems from the lack of a well-accepted definition of land degradation, the kinds of degradation accounted for, uncertainties in the underlying data, and questionable science. Whereas some signs of land degradation are obvious—landslides, gullies cutting through

farmland, dust storms, silted-up rivers, and salinity—others, like loss of soil organic matter and biodiversity, are invisible, and it is hard to measure all these effects consistently. Questions that need to be answered in a scientifically justifiable way include the following: is land degradation a global issue or a collection of local problems? Which are the hardest hit regions? Is it mainly a problem of drylands? Is it associated mainly with farming? Is it related to population pressure or poverty?

THE NDVI DATA AND APPLICATIONS

Surveys of natural resources have always made good use of new technology originally developed for other purposes. The title of an article in *Advances in Space Science* says it all, *The exciting and totally unexpected success of AVHRR in applications for which it was never intended*.^[2] The advanced very high resolution radiometer (AVHRR) carried by U.S. National Oceanic and Atmospheric Administration (NOAA) satellites is actually of low resolution (4 km) compared with the Landsat satellite data already being collected at the time, but its large field of vision and daily global coverage make it ideal for global monitoring. And by chance, the ratio of red (RED) to near-infrared (NIR) radiation measured by the radiometer, the normalized difference vegetation index (NDVI) [$NDVI = (NIR - RED)/(NIR + RED)$], is a good indicator of vegetation dynamics, reflecting leaf area index, the fraction of photosynthetically active radiation (PAR) absorbed by vegetation,^[3,4] and net primary productivity (NPP).^[5] It has been used to estimate vegetation change as an index^[6] or as one input to dynamic vegetation models.^[7,8] These applications are made possible by consistent time series data at spatial resolutions from 20 m to 8 km. The Global Inventory Modeling and Mapping Studies' (GIMMS) data set now comprises more than 30 years' data corrected for instrument calibration, variations in solar angle and view zenith angle, and volcanic dust. Cloud and haze effects are minimized by taking the highest fortnightly value within the composite 8 km² blocks of pixels.^[9,10] Newer sensors that provide subkilometer resolution include Satellite Pour l'Observation de la Terre Végétation, operating since 1998 with subkilometer definition,^[11] and Moderate Resolution Imaging Spectroradiometer (MODIS) carried by NOAA satellites, Terra and Aqua satellites since 2000 and 2002, respectively, which has even higher resolution and independent measurement of the fraction of PAR absorbed (f_{PAR})—a more direct measure of NPP than the estimation via NDVI.^[12] Based on GIMMS data, Fig. 1 depicts the mean global greenness that has increased by 3.8% over a 30-year period ($P < 0.001$; Fig. 2), thanks to atmospheric fertilization.

Land degradation may be defined as a long-term loss of ecosystem function and productivity caused by disturbances from which the land cannot recover unaided. This may be assessed in terms of NDVI, but a decreasing trend does not necessarily mean land degradation; biomass

depends on climate, land use and management, large-scale ecosystem disturbances such as fires, and the global increase in nitrate deposition and atmospheric carbon dioxide. To interpret NDVI trends in terms of land degradation, we have to eliminate false alarms. This can be done for climate, for which a century's consistent data are available, but there are no global time series for land use, which must be examined case by case. And there is an issue of credibility. Translating satellite measurements of reflected solar radiation into the information that policy makers want (loss of production and environmental services, action required to arrest these losses, and the economic and political payback for this action) requires leaps of deduction—some might say imagination.

Global Assessment of Land Degradation

Under the Food and Agriculture Organization (FAO) of the United Nations program Land Degradation in Drylands, the Global Assessment of Land Degradation and Improvement (GLADA) assessed global land degradation by the analysis of trends of climate-adjusted NDVI making use of GIMMS data up to 2003.^[13] Drought effects are screened using *rain use efficiency* (RUE) estimated from the ratio of the annual sum NDVI and annual rainfall. Areas where biomass productivity depends on rainfall variability were identified as those with a positive relationship between NDVI and rainfall. In these areas, the below-normal rainfall is reflected in below-normal NDVI and, usually, increased RUE; when there is decreasing NDVI but steady or increasing RUE, loss of productivity is attributed to drought and these areas are masked. When both NDVI and RUE decline, something else is happening, and these areas are included in the next stage of analysis together with the areas where production is not limited by rainfall. Similarly, *energy use efficiency*, the ratio of NDVI, and accumulated temperature are used to screen trends driven by rising temperatures. All data are expressed at 90% probability; to provide a more tangible measure of land degradation, NDVI was translated into NPP by correlation with MODIS NPP data for the overlapping period from 2000.

The picture revealed was against the received wisdom that reckoned degradation to be worst in the Sahel, the Amazon rain forest, and more generally in drylands; in fact, most of the usual suspects showed improvement. Fig. 3 shows an updated analysis using the GIMMS 3G data set for 1981–2012. The picture differs from the earlier GLADA analysis—not just because of the longer run of data but because of the changes in GIMMS processing to avoid stationarity bias in between-instrument calibration of AVHRR measurements.

The new analysis provides unambiguous answers to most of our policy questions:

- Land degradation is a global issue, with 22% of the land degrading over a 30-year period, representing an NPP

Fig. 1 Global greenness by annual sum NDVI (1981–2011).

Fig. 2 Trend of global aggregated annual sum NDVI (1981–2011).

loss of about 150 million tons but a loss of soil organic carbon orders of magnitude more. The hardest hit areas are Africa, south of the equator, with an arm of degradation extending northward to the Ethiopian highlands and the Nile provinces of Sudan; the Gran Chaco, Pampas, and Patagonia; southeast Asia; the grain belt from Ukraine eastward through south Russia to Kazakhstan; the Russian far east and Northeast China; swaths of high-latitude forest; and the western slopes of the Great Dividing Range in Australia.

- All kinds of land use are afflicted. Cropland comprises 12.6% of the global land area but makes up 15.1% of the total degrading land; grassland occupies 28.8% of the land but constitutes 41.5% of degraded land; and forest is also overrepresented, comprising 23.4% of the land area, but 37% of the degrading area. At the same time, 14% of the land registered increasing productivity.
- The comparison of rural population density with land degradation shows no simple pattern, taking infant mortality and the percentage of young children who are underweight as proxies for poverty, and there is some correlation but a more rigorous analysis is called for.

(77.4% showed no change or was barren). For the country as a whole, drought explains 15% of negative trends; increased rainfall explains 20% and increased temperature explains 38% of the positive trends; what remains may be attributed in some measure to land use and management. But linear trends analysis is a blunt instrument. [Fig. 5](#) illustrates the NDVI trends for five southern provinces that exhibit general improvement, i.e., at the beginning of the time series, the trends showed a cyclical decline that was reversed after about 1995 by the grain-for-green initiative.^[15]

Making allowance for terrain, soil, and land use

We might expect resilience against land degradation to depend on terrain, soil, land use, and management. The Shuttle Radar Topography Mission digital elevation model provides almost global topography at a horizontal resolution of 30 m, but there is no comparable soil information. Regional data are provided by soil and terrain (SOTER) compilations of various surveys in a common format. [Fig. 6](#) depicts the 30-year trend in China with regard to climate-adjusted NDVI by 1:1 million-scale SOTER units. If SOTER units were homogeneous, this procedure would eliminate SOTER effects, but the mapping units are by no means pure—SOTER are normalized only to the extent that differences within mapping units are less than those between units. SOTER residuals ([Fig. 7](#)) reveal the relative departure of each pixel from the trend of its mapping unit, revealing patterns at the landscape scale—where most management decisions are taken. Differences in response to management relate directly to local conditions of SOTER and highlight black spots where production has been declining relative to the local norm and, as a corollary, bright spots that are doing better.

The analysis of land degradation in terms of land use and management is more problematic because no two consecutive land use surveys have used the same classification. In China, comparing the extent of urban areas with areas of

Changing trends

The extended data set reveals some dramatic turnabouts. For instance, in China^[14] ([Fig. 4A and B](#)), there has been persistent and expanding degradation in Tibet and the southwestern provinces, a dramatic increase in degradation across the northeast, and a loss of impetus in many intensively farmed areas despite the increasing application of synthetic fertilizer (from 7 million tons in 1977 to more than 58 million tons in 2012). Over the period 1981–1996, degradation afflicted 1.8% of the country, but 17.5% was improving (80.7% showed no significant change or was barren); between 1996 and 2011, 12.6% of the land was degrading and only 10% showed improvement

Fig. 3 Global negative trend in RUE-adjusted NDVI (1981–2011).

Fig. 4 China: changes in annual sum NDVI – (A) 1981–1996 and (B) 1996–2011.

Fig. 5 China: NDVI trends in five southern provinces (1981–2011).

declining NDVI, it is obvious that, in rapidly industrializing areas, urbanization and linking infrastructure account for much of the decline of NDVI. Using Landsat imagery to assess the influence of land use change, Bai et al.^[14] plotted climate-adjusted NDVI and SOTER residuals against the numerical change in NDVI ascribed to land use. They found a clear relationship between land use change and land degradation—and apparently contradictory trends that might be explained by changes in management, without change in the kind of land use, and by forest fires and outbreaks of pests and disease.

CONCLUSIONS

What NDVI Can and Cannot Do

The aims of GLADA were to provide a globally consistent yardstick for measuring land degradation and to highlight areas where significant biological change is happening—so that they can be investigated and attended to. But follow-up has been disappointing; the results were greeted by disbelief, some published and rebutted but, mostly, behind the scenes and directed to the sponsoring FAO program, which cobbled together a pick and mix of assessments in support

of the old beliefs.^[16] The GLADA, itself, flagged some caveats—most of which have been cleared:

- *The NDVI signal can be saturated at closed vegetation canopy*—so it is more sensitive for cropland and range-land than for forest. But NDVI is useful for forests, and many forests do not have a closed canopy.
- *Maximum composite values may underestimate greenness under cloud and snow cover.* Removal of cloud effects is done by harmonic analysis of the GIMMS data and comparison of global NDVI trends using the reconstructed data, with the original showing no measurable difference—so GLADA is unaffected by cloud cover.
- *Soil moisture affects the NDVI signal in areas of sparse vegetation.* Areas of NDVI less than 0.05 (arid) are not considered.
- *Autocorrelation nullifies trend analysis.* Autocorrelation in the data (whereby any individual value is influenced by the preceding values) is avoided by using annual sum NDVI rather than the fortnightly GIMMS values. But this entails a loss of information; for example, we cannot analyze subtly changing seasonal responses of the NDVI signal that may indicate the nature of any degradation. de Jong et al.^[17] applied the

Fig. 6 Change in sum NDVI by SOTER units (1981–2011).

Cultivation
Desertification
— noncultivation

Fig. 7 Trends of NDVI residuals from SOTER units (1981–2011).

non-parametric Mann–Kendall model that is unaffected by autocorrelation to GIMMS NDVI data and normalized the data for seasonal variations in phenology rather than calendar years (which should be better in the southern hemisphere where growing seasons do not fall neatly within the calendar year). Linear regression and the Mann–Kendal procedure measure different factors: the first measures the annual accumulated photosynthetic activity, whereas the second measures the photosynthetic intensity of the growing season. Each has its own tale to tell, but the close similarity of the patterns of greening and browning revealed by the two models suggests that both are robust.

- *It is hard to separate the effects of climate from the effects of land degradation.* Wessels et al.^[18] used the trend of residuals (RESTREND) to distinguish the human-induced land degradation from the effects of rainfall variability, but this measure is not amenable to economic analysis. Empirical screening of GLADA using RUE produces much the same patterns as RESTREND but loses data. Conijn et al.^[19] disentangled climatic effects and other factors affecting NDVI by modeling biomass production independently according to crop characteristics and global data for climate, soil, and land use. Combining NDVI trends and modeled changes in biomass yields four scenarios, namely *positive $\sum$ NDVI and positive biomass change*—greening might be explained by improving weather; *positive $\sum$ NDVI and negative biomass*—despite worsening weather, greenness has increased, thanks to management or atmospheric fertilization; *negative $\sum$ NDVI and positive biomass*—greenness declines against a trend of expected increase, so land degradation or land use change has outweighed favorable weather; and *negative $\sum$ NDVI and negative biomass*—declining greenness may be explained by worsening weather. Whether the benefits of clearer separation of the climatic drivers are worth the substantial effort required is moot. The spatial variability of rainfall in drylands makes interpolation of the sparse point measurements problematic; biomass modeling using just a few vegetation types and predefined management has its own limitations. It is not easier to verify changes in the calculated biomass using independent data than to verify changes in NDVI.
- *Measurement of land degradation NDVI trends underestimates the problem.* Farming everywhere is running down stocks of soil organic matter that supplies plant nutrients; maintains infiltration, available water capacity, and resilience against erosion; and fuels soil biodiversity. Over the 20th century, 60% of soil and biomass carbon has been lost through land use change;^[20] Chernozem, the best arable soils in the world, has lost 30–40% of its organic carbon^[21]—yet they yield abundantly till a tipping point is reached and then the system flips—like the Dust Bowl. The NDVI data show that

heavy use of fertilizer across much of China, the Indo-Gangetic Plain, Europe, the Midwestern United States, and Southern Brazil is no longer accompanied by increasing production but may be concealing soil degradation.

Policy Applications

The NDVI data demonstrate that land degradation is a global issue and, by and large, present policies are failing to arrest it. Arresting land degradation, not to mention remediation, requires long-term investment. This may yield high social returns, but budgetary constraints demand prioritization—so decision-makers need information about the location, extent, and severity of degradation, and an early warning system so that timely interventions may be made in specific areas where land and water resources are overloaded. Thirty years of NDVI data show natural cyclical changes and, also, changes in these trends beyond individual drought cycles. The NDVI trends translated in terms of NPP provide a robust measure of land degradation that is amenable to economic evaluation. Deviation from the local or regional trend can also provide an early warning system: for instance, residuals from SOTER units that, to some extent, normalize the data for local soils, terrain, and climate. But greening and browning cannot be other than a proxy for land improvement and degradation: they identify places where significant biological change is happening but tell us little about the nature of these changes and nothing about the drivers.

The resolution of GIMMS AVHRR data is a limitation in that an 8-km pixel integrates the signal from a wider surrounding area. Many symptoms of severe degradation, such as gullies, rarely extend over such a large area: they must be severe indeed to be seen against the signal of surrounding unaffected areas. Annually aggregated data also lose much of the detail within the data set, but the use of the harmonic analysis of NDVI time series algorithm to eliminate the effects of haze, snow, and cloud cover and integration with auxiliary data sources such as climate and land use information open the door to more forensic analysis of the wealth of information within the data set. And newer sensors offer subkilometer resolution and, in the case of MODIS, a more direct measure of NPP.

Degradation: Off-Farm Economic Implications

Dennis Wichelns

International Water Management Unit, Colombo, Sri Lanka

Ellen Burnes

MWH Americas, Inc., Sacramento, California, U.S.A.

Abstract

We present an economic model of the off-farm impacts of soil degradation. Our goals are to describe why off-farm impacts occur and to identify policies that might be helpful in motivating reductions in negative impacts. We also examine policies that can motivate farmers to adopt technologies that generate positive off-farm impacts. The appropriate framework for this analysis is a social optimization model that includes the net revenues generated by agriculture and any costs and benefits due to off-farm impacts.

INTRODUCTION

Farm-level decisions regarding inputs and outputs often have impacts on other farmers and on natural and environmental resources. Some of the impacts involve soil degradation, either directly or through impacts on complementary inputs that enhance soil productivity. For example, excessive irrigation on one farm can generate surface runoff that carries sediment into irrigation channels used by other farmers. Excessive withdrawals of water from a canal or aquifer can reduce the volume of water available to other farmers in a region. Soil productivity is reduced on those farms if the water supply becomes inadequate to support crop production. Some farm-level decisions have positive impacts on soil productivity and environmental quality. Farmers installing sub-surface drainage systems might relieve the pressure from a shallow water table for several neighbors. Farmers who use sprinkler or drip irrigation systems might reduce their withdrawal of water from regional sources, while also reducing surface runoff and deep percolation.

A SOCIAL OPTIMIZATION MODEL

The net social benefits of agricultural production include the net revenues earned by farmers and the costs or benefits of any off-farm impacts. The appropriate framework is intertemporal because 1) farmers seek to maximize the present value of the sum of net revenues earned over time and 2) soil is a durable resource. Production decisions in any year can affect soil productivity in ways that influence crop and livestock choices, input use, and yields in many subsequent years. Decisions can also have long-term impacts on soil and water resources used by other farmers

and on environmental resources that generate public benefits. Pesticides and salt that enter streams or aquifers via surface runoff or deep percolation can have long-lasting impacts on water quality. The waterlogging and salinization that result from excessive irrigation or inadequate drainage can reduce soil productivity for many years.

The objective function of the social optimization model includes a set of J crop and livestock activities and T time periods. Total revenue, total costs, and off-farm impacts are shown as functions of land, labor, capital, and other inputs. This model differs from the farm-level optimization model by the inclusion of off-farm benefits and damages. In addition, the objective function involves the maximization of the value of net benefits rather than net revenue

$$\begin{aligned} \text{PVNB} \sum_{t=0}^T \sum_{j=1}^J [& P_{jt} Y_{jt}(L_{jt}, B_{jt}, K_{jt}, A_{jt}) \\ & - TC_{jt}(L_{jt}, B_{jt}, K_{jt}, A_{jt}) + OFB_{jt}(L_{jt}, B_{jt}, K_{jt}, A_{jt}) \\ & - OFD_{jt}(L_{jt}, B_{jt}, K_{jt}, A_{jt})] [1 + r]^{-t} \end{aligned} \quad (1)$$

where PVNB is the value sum of net benefits, P_{jt} is the price of crop or livestock product j in year t , Y_{jt} represents the output of crop and livestock products, TC_{jt} represents the total costs of production, OFB_{jt} represents the off-farm benefits generated by producing product j in year t , OFD_{jt} represents the off-farm damages caused by production, L_{jt} is the amount of land used in each production activity, B_{jt} is the amount of labor, K_{jt} is the amount of capital, A_{jt} represents all other inputs, and r is the appropriate discount rate.

We use this model to analyze the off-farm impacts of farm-level decisions, such as soil erosion, waterlogging, and salinization. Our goals are to examine the causes of

off-farm impacts and to describe public policies that might reduce those impacts in some areas.

OFF-FARM BENEFITS AND DAMAGES

Farmers have an economic incentive to maximize the present value of net returns from crop production described by the first two terms in the optimization model ($P_{jt}Y_{jt}$ minus TC_{jt}). In the absence of appropriate policies, farmers often have little incentive to consider the off-farm benefits or damages generated by their activities (OFB_{jt} and OFD_{jt}).

Farmers seeking to maximize net revenue will equate the marginal cost of their decisions with the expected marginal benefits, as viewed from their perspective. The optimizing criteria that guide farm-level decisions will not include the positive or negative impacts on other farmers or environmental resources. As a result, farm-level choices will not be consistent with those that would maximize the present value of net social benefits. From the public's perspective, farmers will use too few inputs that generate off-farm benefits and too many inputs that generate off-farm damages.

The divergence between farm-level and socially optimal input levels can be described using diagrams that depict incremental costs and benefits. For example, the farm-level incremental cost (also called the marginal cost) of obtaining groundwater for irrigation might be considered constant within a season, whereas the marginal benefit declines with the amount of water applied per hectare. The farm-level profit-maximizing water application (W_F) is found by equating the marginal benefit (MB_F) and marginal cost (MC_F), as shown in Fig. 1. In many areas, groundwater extraction and irrigation generate off-farm impacts, such as a reduction in water available for other farmers and surface runoff that carries sediment. The incremental off-farm impacts must be added to the farm-level marginal costs to determine the socially optimal water application, W_S

Fig. 1 The marginal costs and benefits of water applied for irrigation.

Fig. 2 The marginal costs and benefits of vegetative filter strips.

(Fig. 1). In the absence of appropriate policies, farm-level input use will exceed the socially optimal level when off-farm marginal costs (MC_{OF}) are non-zero.

Farmers can use vegetative filter strips to reduce the sediment transport from farms. Farm-level benefits include the retention of topsoil and nutrients, whereas off-farm benefits include lower costs of removing sediment and nutrients from waterways. The incremental cost of installing vegetative filter strips might be constant within a season, whereas the farm-level incremental benefits likely decline with the area planted in filter strips. The optimal area from the farmer's perspective (A_F) is found by equating the marginal benefit (MB_F) and marginal cost (MC_F), as shown in Fig. 2. The incremental off-farm benefits must be added to the farm-level marginal benefits to determine the socially optimal area, A_S (Fig. 2). In the absence of appropriate policies, the area planted in vegetative filter strips will be smaller than the socially optimal area when off-farm marginal benefits (MB_{OF}) are non-zero.

POLICY IMPLICATIONS

Economic incentives and other policies can be implemented to encourage farmers to reduce their use of inputs that generate off-farm damages and to increase their use of inputs that generate off-farm benefits. Per-unit taxes and subsidies on inputs will raise or lower the farm-level marginal costs of inputs. Per-unit taxes on irrigation water will motivate improvements in water management, whereas per-unit subsidies for vegetative filter strips will encourage greater planting activity. Low-interest loans and cost-share programs can encourage greater farm-level investment in production methods that reduce off-farm damages or increase off-farm benefits.^[1]

Public policies designed to reduce soil degradation must be chosen carefully, as farm-level responses will vary among regions because of differences in existing institutions and cultural perceptions.^[1-4] Farmers must consider

many components of public policies when selecting crop production activities, technologies, and variable inputs. Commodity price support programs motivate higher levels of production for some crops, whereas conservation reserve programs encourage farmers to retire land from agricultural production. The appropriate empirical values of taxes, subsidies, and other incentives will vary among regions according to differences in the incremental costs and damages of agricultural production and with differences in other policies that influence farm-level decisions.

The justification for policy intervention to reduce off-farm damages will also vary among regions. Some authors suggest that the magnitude of off-farm damages from soil degradation worldwide is quite large,^[5,6] whereas others suggest the magnitude is reasonable.^[7,8] Most authors probably would agree that off-farm impacts are severe in some areas^[9] and that policy intervention is needed to increase social net benefits in those areas. Policies that motivate advances in knowledge are needed to address local issues regarding soil degradation and to ensure future improvements in aggregate productivity.^[8,10]

CONCLUSION

Market prices for inputs and outputs often do not reflect the off-farm impacts of production activities, such as those arising from soil degradation. Public policies can motivate farmers to consider off-farm benefits and damages, but policy intervention is not always appropriate. The need for policy intervention and the empirical values of parameters that will motivate optimal input use will vary among regions, and over time, with differences in existing institutions and in the off-farm impacts of farming activities.

Degradation: Physical

Michael A. Zebisch

Anthony R. Dexter

Institute of Soil Science and Plant Cultivation (IUNG), Pulawy, Poland

Abstract

Different forms of soil physical degradation go along with each other—they are interlinked and not always clearly distinguishable from each other. Different types of soil physical degradation cannot be distinguished uniquely in terms of simple cause-and-effect relationships. The causes and effects are often the same for several types of degradation. The main types of soil physical degradation are characterized by the different sets of processes involved and responsible for the degradation. Deterioration of soil structure is the overriding and more general form of soil physical degradation. Compaction, sealing and crusting, and hardsetting are important special types of soil structure breakdown with important implications for soil management and land use.

INTRODUCTION

There is no accepted standard terminology concerning the definitions of terms used to describe and classify soil degradation. It is difficult to draw clear boundaries between the different types of soil degradation because, as with any complex natural system, there are a lot of interrelationships and interdependencies between chemical, biological, and physical degradation processes in the soil. Different forms of soil physical degradation go along with each other—they are interlinked and not always clearly distinguishable from each other. The International Union of Soil Science^[1] has proposed a comprehensive terminology for soil physical processes and characteristics, but the use of terms is not coordinated and sometimes confused. The classification of the different types of soil physical degradation is, therefore, not clearly differentiated. For example, it may be argued that waterlogging is not a degradation type on its own. It is rather a consequence of other physical degradation processes and caused by a reduction in permeability due to soil structure breakdown or compaction. Because of impeded water entry and movement, waterlogging can also lead to other types of degradation, such as salinization. These examples illustrate the fuzziness of boundaries between soil physical degradation and other forms of degradation. Different types of soil physical degradation cannot be distinguished uniquely in terms of simple cause-and-effect relationships. The causes and effects are often the same for several types of degradation. Fig. 1 depicts the cause-and-effect system typical for soil physical degradation.

The main types of soil physical degradation described in this entry are characterized by the different sets of processes involved and responsible for the degradation. Deterioration

of soil structure is the overriding and more general form of soil physical degradation. Compaction, sealing and crusting, and hardsetting are important special types of soil structure breakdown with important implications for soil management and land use.

LOSS OF SOIL STRUCTURE

There are a number of definitions of soil structure in the literature. Many of these describe the arrangement of primary particles into aggregates of different sizes and shapes and the associated pore spaces between them. Therefore, a structured soil is heterogeneous, whereas a degraded, structureless soil is homogeneous. A more general definition is “the spatial heterogeneity of the different components or properties of soil.”^[2] Soil structure significantly influences all processes that take place in the soil. It influences water infiltration (and hence runoff), the movement of water within the soil, and the amount of water that can be stored in the soil. Therefore, it has a direct influence on soil erosion. Soil structure also determines aeration levels in the soil, which are essential for the oxygen supply to roots, soil fauna, and for aerobic microbial activity. High soil strength impedes seedling emergence and root growth and also makes tillage more difficult and more energy demanding. These functions demonstrate the role and importance of the size and continuity of pores in the soil for the movement of soil and water into and within the soil.^[3] Not only the soil structure but also the stability of the structure is of major importance. Structural stability determines the ability of a soil to withstand imposed stresses without changes in its geometric structure and functions. These stresses may be

Fig. 1 Simplified cause-and-effect system of soil physical degradation.

Source: Adapted from Dexter^[2] ©1988, Shaxson^[3] ©1999, Gabriels, Horn et al.^[4] ©1998, Lal & Ahmadi^[5] ©2000, and Arvidsson^[6] ©2000.

due to rapid wetting, raindrop impact, wheel traffic, and excessive tillage.

Soil physical degradation reflects soil structure breakdown or homogenization, when soil aggregates are destroyed by internal or external forces.^[4] Internal forces are applied when entrapped air breaks out of soil aggregates upon flooding. External forces appear in the form of rain impact or pressure and shearing forces exerted by animal trampling, wheel traffic, and tillage implements. Depending on the water content, this results in either pulverization or compaction of the soil. Soil physical degradation, however, depends not only on the degrading forces and stresses but also on the stability of a soil to withstand these stresses and its resilience to recover from different levels of short-term and long-term degradation.

Not all activities that break down soil are necessarily degrading. Appropriate use and management of the soil also include measures to maintain—and improve—the resilience of soils. Appropriate soil tillage aims at producing soil structural conditions that improve plant establishment and growth. However, excessive tillage with high-energy inputs can result in losses of soil organic matter and can increase the amount of readily dispersible clay. Both of

these consequences can result in decreased structural stability and hence structure breakdown. Such a degraded soil will be weaker when wet but stronger when dry and will be more difficult to manage under all conditions.

Compaction

Compaction describes the state, or the increase, of “compactness,” i.e., bulk density, of a soil. Compared with its undisturbed condition, a compacted soil exhibits reduced total pore space, especially because of a drastic reduction of the macropores and a pronounced discontinuity of the pore system within the profile.^[3] This affects the conductive properties of the soil and reduces its ability to retain air and water. Hence, plants growing under high evaporative demand suffer more from compaction than plants growing under low evaporative demand.^[7] Compaction also inhibits root penetration and development, thus affecting nutrient uptake and, consequently, plant growth. [Table 1](#) shows examples of the effects of soil compaction on the yields of different crops, due to tillage and heavy machinery.

The most important cause of compaction is off-road wheel traffic and the use of heavy machinery in mechanized

Table 1 Crop yield decline due to soil compaction.

Crop	Soil type	Selected control parameter	Yield trend	Country	Source
Wheat	Sandy loam	Penetration resistance increased from 0.83 to 1.29 MPa; bulk density increased from 1.68 to 1.78 Mg m ⁻³ after two crops	Decrease between 12% and 38%	Pakistan	[8]
Sorghum (fodder)	Sandy loam	As above, but after one crop	Decrease between 14% and 22%		
Spring barley Oilseed rape Winter wheat	Loam and sandy loam	Saturated hydraulic conductivity reduced by about 90% after one crop	Average overall decrease of only 1%, non-significant	Sweden	[9]
Corn (grain)	Silt loam	Bulk density was correlated with tillage type, i.e., lowest under chisel plowing (1.25 Mg m ⁻³) and highest under moldboard plowing (1.31 Mg m ⁻³) after 11 cropping seasons	Under regular machine traffic, yield decline was 5% for 7.5 Mg axle load and 10% for 7.5 Mg axle load over 11 cropping seasons	Ohio, U.S.A.	[5]
Barley	Clay loam	Bulk density increased from 1.15 to 1.50 g cm ⁻³ after one crop depending on depth, type of tillage, and equipment used	Yield declined from around 1300–1000 kg ha ⁻¹	Jordan	[6]

agriculture.^[7,10] In the upper part of the soil, mainly the contact pressure of moving vehicles and the shearing effects of the wheels determine compaction. At a greater soil depth, the axle load is more important. The bulk density of the soil increases with the weight, i.e., pressure, exerted by vehicles and machinery, and also increases with increasing soil water content and the number of passes of the vehicles and machinery over the soil surface. Soils with high clay contents and well-developed pore systems are generally more compressible than sandy soils. Tillage practices also influence the degree of topsoil compaction. Within the annual cropping cycle, the topsoil undergoes changes in its bulk density. To a large extent, plowing alleviates the effects of topsoil compaction produced by the crop husbandry measures and harvesting activities carried out during and after the cropping season. However, seedbed quality may be severely reduced if the topsoil was severely compacted in the previous year. A cumulative effect of compaction caused by heavy machinery is often observed after several years. Soil compaction increases the demand for tillage. It has been shown that compaction reduces the range of water content over which tillage can satisfactorily be done and therefore reduces the opportunities for tillage.^[11]

For practical purposes, two main types of soil compaction can be distinguished, namely the surface layer compaction and subsoil compaction.

Surface layer compaction describes the compaction in the upper part of the soil profile, i.e., in arable soils usually the plow layer. Compaction in the surface layer is dynamic and changes significantly over the cropping season, increasing with increasing machinery passes over the field and decreasing again with primary tillage for seedbed preparation for the following season. In reduced tillage systems, the effects of soil compaction

build up and tend to be more lasting than in plow systems.^[5] These effects seem to be more pronounced in sandy soils than in clay soils, because of their lower capacity to maintain a continuous macropore system.^[2] Adequate tillage effectively reduces soil compaction in the surface layer and its effects.

Subsoil compaction affects soils beyond the surface layer at depths >30 cm. It is caused by heavy machinery, especially those with high axle loads.^[5,10] Swelling–shrinking, freezing–thawing, and biological activities can alleviate compaction to a certain extent. However, these processes are not usually effective beyond a depth of 35 cm. Subsoiling using specially designed equipment can in some cases alleviate subsoil compaction, but it is very energy demanding. Subsoiling should be attempted only when the whole soil profile is drier than the plastic limit (or lower Atterberg limit) of the soil, otherwise more harm than good may be done. Soil at these depths can be dried sufficiently only by plant roots. However, the compaction may prevent the necessary root growth. In many situations after subsoiling, the soil recompacts readily to be denser than it was before sub-soiling because of the destabilization of the soil caused by the mechanical energy input from the subsoiling operation. Compaction should be considered to be an irreversible, permanent form of degradation.

Sealing and Crusting

Seals and crusts are consequences of rain and flooding on unprotected soil surfaces. Under the impact of raindrops and the “soaking” effect of water, the bonds that hold the particles together become weak, and the soil aggregates tend to fall apart. Individual particles become separated. These particles become rearranged, and the finer particles

tend to be washed into the cavities of the surface. There they form a very thin (1–5 mm) and dense layer that clogs the soil pores and seals the surface. This process is also referred to as capping. These seals are usually very elastic. Typical characteristics of soil seals are that they do not crack and cannot be removed from the surface.

Soil crusts are formed by the same processes that form seals. They are much thicker than seals (usually 5–20 mm), they can be separated easily from the soil surface, and they crack upon drying. Crusts are typically formed on soils with high contents of non-swelling clay susceptible to dispersion. Seals that become hard upon drying are frequently also termed crusts.^[12] Soils with a high content of fine or very fine sand or silt are especially prone to sealing and crusting. The presence of exchangeable sodium in the soil can enhance clay dispersion and thus contribute to seal and crust formation.

Depending on the dominant processes, three types of seals or crusts are distinguished.^[4,13] *Structural crusts* are a result of physical forces, i.e., raindrop impact, animal trampling, wheel traffic, and flooding. *Slaking crusts* are formed as a result of the disintegration of the soil structure when in contact with water. This can take the form of chemical dispersion of the clay due to, e.g., the presence of exchangeable sodium, mainly in sodic soils, or of the slaking of the soil into microaggregates. *Depositional crusts* are formed by the translocation and deposition of fine particles, e.g., by erosion processes and on irrigated fields.

The main direct effects of seals and crusts are a decrease in infiltration and hence increase in surface runoff and soil erosion and an obstruction to seedling emergence.

Hardsetting

Hardsetting is a result of structural breakdown and reconsolidation of soil under repeated wetting and drying cycles.^[12] The result is a hard, homogeneous mass difficult—if not impossible—to till and therefore very restrictive for soil use and management. Hardsetting takes place in two stages. First, the soil structure breaks down under wetting. This process is, in principle, the same for all forms of soil physical degradation and is influenced, as described before, by a complex set of interacting physical, chemical, and biological conditions and processes. The second stage is characterized by the drying of the soil—without a significant regain of structure—and hardening of the soil mass. During this second stage, effective stresses due to the menisci of water films and the water matric potential contribute to the consolidation process. The main effect of hardsetting—an increase in soil tensile strength—increases with each wetting and drying cycle. Soils that tend to hardset usually are low in non-swelling clays and have moderate levels of silt and fine sand.^[12] In soils that release soluble salts when moist, the effects of hardsetting upon drying are usually increased. Hardsetting

can affect soils to depths of 20–30 cm. Because of their extremely high tensile strength, hardsetting soils are very difficult to till when dry. To offset the effects of drying, tillage has to be timed after rainfall or irrigation before the hardening of the soil occurs. This restricts the time available for effective soil tillage.

Hardsetting processes affect many soils, but this does not necessarily make them hardsetting soils. More sandy soils with a weaker structure do not usually become too hard to till upon drying, although they also undergo hardsetting processes. These soils develop features and problems related to hardsetting, but they can still be tilled without major limitations and constraints. Typical effects of hardsetting are the obstruction to seedling emergence and increased resistance to root growth.

CAUSES AND EFFECTS OF SOIL PHYSICAL DEGRADATION

The main causes of soil physical degradation, i.e., the breakdown of the soil structure, are inappropriate land-use and soil management practices. All “exploitative” practices will ultimately lead to degradation and hence reduced soil productivity. The basic detrimental effects of certain practices—or of their neglect—on different soil properties are known. But their specific contribution to the breakdown of the soil structure in a specific location also depends on the other prevalent practices and factors. The same set of circumstances applies to the effects that soil physical degradation has on soil productivity and the environment.

In highly mechanized systems, heavy machinery and excessive tillage are important factors of degradation. In the developing world, land not suitable for cultivation, such as drylands or steep terrain, is increasingly being cropped. The cultivation and husbandry practices associated with these land use systems are largely responsible for degradation. The systems themselves are, in the long term, also largely affected by them. Fig. 1 depicts the causative factors and effects that lead to soil physical degradation. It shows that inappropriate soil and land management leads to an array of different types of soil physical degradation. Ultimately, soil physical degradation leads to reduced plant growth, crop yields, and soil productivity.

The soil environment is very dynamic, and changes in one property may affect the response of another property to different degrading stresses. Also, climatic conditions, which play an important role in degradation, vary from season to season.^[5]

MEASURES TO MITIGATE AND REDUCE SOIL PHYSICAL DEGRADATION

The best way to prevent and control soil degradation is by using the land and soil according to their capability and

observing natural constraints, such as terrain and climatic conditions. This is best done by what is commonly referred to as “appropriate” soil and land use. However, the conditions determining the suitability of soil use are always location specific. Therefore, there is no single universally valid system of appropriate farming. All measures that lead to an optimization of plant cover and plant population, and maintain a stable structure, are suited to prevent soil physical degradation.

ASSESSMENT AND MEASUREMENT OF SOIL PHYSICAL DEGRADATION

Because of the high degree of interaction between the different physical, biological, and chemical factors and processes involved, the quantification of soil physical

degradation in its totality and its effects on plant growth are extremely difficult. There are no standard, objective methods to assess soil physical degradation in its entirety.^[2,4,7,13] In practice in most cases, it is usually a subjective assessment by specialists, based on their individual experience. A well-known example of this is the methodology used by the Global Assessment of Human-Induced Soil Degradation project.^[14]

However, many basic soil properties that are altered by physical degradation can be measured objectively and quite easily. Changes over time in these characteristics can be used to estimate the influence of a single or a set of properties on plant growth and soil productivity. Table 2 lists a number of simple field and laboratory methods that can be used to measure and characterize these properties.

One of the two common basic concepts is the assessment of the severity of past and ongoing degradation.

Table 2 Examples of simple (indicative) tests to assess soil characteristics important for the evaluation of soil physical degradation.

Soil characteristic (indicator)	Field assessment (test)	Laboratory assessment (test)
Compaction	Bulk density (e.g., sand-replacement method) Penetration resistance (cone penetrometer) Shear vane test	Bulk density (using soil cores) Precompaction stress
Total porosity	From bulk density (above) assuming a particle density of 2.65 g cm ⁻³	Pycnometer test
Pore space distribution	N.P.	Calculation from bulk density Water-retention at various potentials
Clay dispersion	“Emerson (1967) test” ^[11]	Gravimetric method (Pipette test) Turbidimetry
Aggregate stability	“Emerson (1967) test” ^[11]	Wet sieving
Aggregate strength	Feel (crushing between thumb and first finger)	Tensile strength test (crushing force)
Infiltration	Double-ring infiltrometer Tension (disk) infiltrometer	
Permeability	Constant-head permeameter	Constant-head permeameter
Hydraulic conductivity	Tension (disk) infiltrometer	Falling-head permeameter
Runoff generation	Rainfall simulation	Rainfall simulation
Soil organic matter content	N.P.	Loss on combustion
Walkley Black method		
Texture (particle-size distribution)	By feel	Sedimentation test
Crust strength	Cone penetrometer test Crop-emergence count	Cone penetrometer test Modulus of rupture test
Water-holding capacity	Neutron probe or TDR 2 days after heavy rain	Soil cores
Aeration status	Air permeability Redox potential Oxygen diffusion rate Oxygen diffusion rate	Air-filled porosity Air permeability Redox potential
Soil-particle detachment	Rainfall simulation and sediment sampling	Rainfall simulation and sediment sampling

This is usually a comprehensive assessment of actual field conditions. The other concept is the assessment of the susceptibility of a certain soil to degradation under a variety of soil-use and soil management practice scenarios. Often, treatments are simulated in the laboratory. Another aspect of concern is the impact of climate change on the sensitivity of soils to physical degradation.

Degradation: Quality and

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Understanding principal processes, factors, and causes of soil degradation is an important prerequisite to our ability to reverse the degradative trends and to preserve a healthy state of global environment. Being a complex problem, it requires a systematic and coordinated effort to effectively address the major issues involved. These issues include: 1) obtaining reliable estimates of the land area affected by different soil degradative processes; 2) standardizing definitions and methods of assessment of soil degradation; 3) evaluating on-site and off-site impacts of soil degradation; 4) developing appropriate measures of soil restoration; and 5) assessing economic and environmental impacts of restoring degraded soils and ecosystems.

INTRODUCTION

Soil degradation is defined as diminution of soil quality in terms of its existing and potential productivity and/or reduction in its ability to be a multipurpose resource by both natural and anthropogenic causes.^[1,2] A decrease in soil quality implies adverse changes in soil properties and processes with a negative effect on the soil's life-support systems.^[2–4] Soil degradation has both agronomic and ecological consequences. Agronomically, soil degradation leads to loss of production and renders an ecosystem unsustainable under the specific land use.^[2] Ecologically, soil degradation leads to pollution of natural waters, emission of radiatively active gases into the atmosphere, decrease in soil biodiversity, etc. Soil degradation is the result of interactive effects of processes, factors, and causes or management practices.

PROCESSES OF SOIL DEGRADATION

The processes of soil degradation involve mechanisms, actions, and interactions that affect the soil's: 1) resilience or capacity of self-regulation; 2) life-support processes or productivity; and 3) ability to moderate environments. The principal processes of soil degradation are briefly shown in [Fig. 1](#) and [Table 1](#).

Physical Processes

These processes lead to adverse changes in soil's physical, mechanical, or hydrological properties. Principal among these processes is the decline in soil structure, which manifests in crusting, compaction, impeded surface and subsoil drainage, and the poor or limited aeration. A reduction in aggregation and the dispersion of clay lead to a loss of clay

through erosion and eluviation. Accelerated soil erosion is a major soil degradative process, which has potentially severe ecological and economic consequences, and has local, regional, or global impacts.

Chemical Processes

These processes lead to undesirable changes in soil chemical (reaction) and nutritional (fertility) properties. Soil chemical degradation involves adverse changes in: 1) properties and processes that regulate nutrient capacity and intensity; 2) soil's ability to inactivate or denature toxic substances; 3) the soil's chemical balance, leading to elemental toxification [Al, manganese (Mn), and salts] and nutrient deficiencies; and 4) the quality of natural water, atmosphere, and the general environments.

Biological Processes

These processes affect soil biodiversity. The principal effect of biological degradation is a decline in soil organic matter content, a reduction in biomass carbon, and a decrease in the activity and species diversity of soil fauna and flora.

NATURAL VS. ANTHROPOGENIC PROCESSES

Soil degradative processes may be natural or anthropogenic. Natural processes are generally slow, soil forming or pedological mechanisms, and their effect is felt over the geological time-span. In contrast, anthropogenic processes are rapid, highly destructive, and their effect is felt over human time-span. Some important natural and anthropogenic processes of soil degradation are listed in [Table 2](#) and are briefly described as follows.

Fig. 1 Principal processes of soil degradation.

Source: From Lal & Stewart.^[5]

Natural Processes

One of the natural degradative processes is “laterization,” which is a process of iron accumulation in soils. At its extreme, the process involves intense weathering and leaching. Intense weathering leads to the breakdown

of all minerals except quartz. Intense leaching of soil removes all the soluble salts and some of the iron (Fe) and aluminum (Al). These processes lead to a predominance of kaolinite and a depletion of plant-available nutrients. As a result, high concentrations of Fe and Al cause complex fertility management problems.

Hard-setting is another natural process. Hard-setting soils are characterized by weakly cemented surface horizons in deeply weathered soils of low inherent fertility and low soil organic matter content.^[6] Such soils have massive, single-grain or weak pedality of the surface. These soils set hard on drying and have a narrow range of moisture content at which they can be managed. Hard-setting

Table 1 Processes of soil degradation.

Physical processes	Chemical processes	Biological processes
Decline in soil structure, e.g., compaction, crusting, etc.	Leaching and acidification	Decline in soil biodiversity
Accelerated erosion by water, wind, gravity, and glaciation	Nutrient depletion	Decrease in soil organic matter content
Decrease in effective rooting depth	Nutrient imbalance: i) toxicity, e.g., Al, Mn, Fe ii) deficiency, e.g., P	Reduction in soil biomass carbon
Anaerobiosis or excessive wetness	Sodication	Increase in pests and pathogens
Excessive drainage or droughtiness	Laterization	

Table 2 Natural and anthropogenic processes of soil degradation.

Natural processes	Anthropogenic processes
Set-in-motion by natural causes	Set-in-motion by human intervention
Laterization	Accelerated erosion
Fragipan formation	Impeded surface drainage
Clay pan formation	Soil compaction
Hard-setting	Fertility depletion

characteristics are accentuated by physical and biological processes of degradation.

Pan formation within the soil profile is another natural degradative process. There are two principal types of pans. Fragipans are pedogenic subsurface horizons characterized by their medium texture; a high content of silt, very fine sand, and low-to-moderate clay content; high bulk density; low organic matter content; and brittle when moist and hard when dry.^[1] These pans affect rooting depth and plant-available water reserves. In contrast to Fragipans, clay pans are not brittle and may not have high density. *In situ* formation of a clay pan in the B horizon happens due to translocation of fine clay to the subsoil. The physical barrier formed by the clay pan is root-restrictive and can also lead to impeded drainage.

Anthropogenic Processes

Human activities have created the formation of “anthropic soils.” Anthropogenic soils may be due to urbanization, waste disposal, or other drastic perturbation.

FACTORS AND CAUSES OF SOIL DEGRADATION

Factors of soil degradation are ecosystem characteristics. Notable among these are climate (e.g., rainfall and temperature), terrain characteristics, and vegetation (Fig. 2). Factors are agents and catalysts and accentuate the rate of different processes of soil degradation. The causes of soil degradation are anthropogenic activities, which grossly alter the influence of processes and factors. Important causes of soil degradation include agricultural activities, industrial activities, and urbanization (Fig. 3 and Table 3). The causes of degradation are driven by demographic pressure, human needs, and other issues related to the human dimension. Consequently, increase in demographic pressure aggravates the effects of processes and factors of soil degradation.

EFFECTS OF SOIL DEGRADATION

Soil degradative processes are influenced strongly by biophysical factors and socioeconomic causes (Fig. 4). The

effects of physical processes of soil degradation are exacerbated by anthropogenic activities in ecologically sensitive ecoregions. The soil erosion problem is extremely severe when sloping lands and shallow soils are cultivated for row crop production in ecologically sensitive ecoregions such as the Himalayan–Tibetan ecosystem, Andean region, the Caribbean, and the West African Sahel. Deforestation in ecologically sensitive regions can cause severe degradation of soil and water resources, e.g., tropical rainforest ecosystem.

Degradation of soil has both economic and ecologic consequences. The most direct and economic effect of degradation of soil resources is the loss of agricultural productivity. The adverse effects of soil degradation on productivity are accentuated by a progressive decline in the per capita arable land area at national and global scales. The per capita arable land is rapidly decreasing due to an increase in population and the degradation of soil resources. Global per capita arable land area of 0.3 ha in 1985 declined to 0.23 ha in 2000, 0.15 ha by 2050, and 0.14 ha by 2100. Countries with per capita arable land area of less than 0.15 ha were 5 in 1960, 23 in 1990, and will be 50 in 2025.^[7] Mismanagement, neglect, and exploitation can deplete or even ruin the fragile soil resources.

While the per capita arable land area is decreasing, its productivity is also being reduced by several processes of soil degradation, e.g., erosion, desertification, leaching, etc. The effects of soil degradation on productivity are not easily understood because they are often cumulative and may be observed long after the degradation has occurred. Furthermore, productivity is the net result of all factors of production, including climate, and the effects are masked by management and the prevailing weather conditions. In addition to the direct effects of degradation on productivity, there are many indirect or hidden effects due to alterations in soil properties. In fact, there are no reliable estimates of worldwide loss in productivity due to different processes of soil degradation.^[8,9]

Ecologic consequences of soil degradation are major environmental concerns. The annual discharge of chemicals to world rivers is phenomenal and rapidly increasing. Chemical discharge into natural waters from agricultural land may be from fertilizers and pesticides, feedlots, and

Fig. 2 Major natural and anthropogenic factors affecting soil degradation.

Source: From Lal & Stewart.^[5]

Fig. 3 Principal causes of soil degradation.

Source: From Lal & Stewart.^[5]

from sediment. Risks of agrochemical contamination of natural waters are extremely high in both developing and developed economies.

Emission of radiatively active gases from soil-related processes is another principal ecologic consequence of soil degradation. The emission of CO₂ and other greenhouse gases (e.g., CH₄, N₂O, and NO_x) by soil erosion can be enormous.^[10] Yet, world soils can be a major source or sink for radiatively active gases depending on the land use and management system adopted.^[11]

GLOBAL EXTENT OF SOIL DEGRADATION

The problem of soil degradation has been accentuated drastically by changes in land use witnessed since the 18th century. Despite the widespread awareness about the problem, exact estimates of the extent and severity of soil degradation are not known. According to some estimates, about 2.0 billion hectares of land is degraded to some degree out of the world's total land areas of 13.4 Bha.^[12,13] Furthermore, Asia and Africa combined account for a total of 1.24 Bha of degraded land. The most predominant degradative processes are the

accelerated erosion by wind and water, chemical degradation and soil fertility depletion, and physical degradation resulting from a decline in soil structure (Table 4). Estimates of soil degradation in arid climates, due to wind erosion and desertification, are equally alarming (Table 5).

DATA ACCURACY AND RELIABILITY

Statistics, such as those shown in Table 5, play an important role in creating awareness about the hazard, and in formulating a global strategy in addressing it. Indeed, if these statistics are correct, the challenge they present to the human race is one of the greatest because soil resources are finite and non-renewable over the human time-span.^[14,15] Even though the statistics can be approximately correct, it is a matter of greatest urgency for decision makers to do something about it. However, careful analyses of the data may reveal several problems:

1. There may be a problem with the definition. The term soil degradation is vague and highly subjective. To avoid ambiguity, soil degradation needs to be defined

Table 3 Causes of soil degradation.

Anthropogenic causes		Natural causes
Agricultural activities	Industrial activities and urban development	Climate and land
Deforestation: felling trees and biomass burning	Mining: surface or strip mining and subsurface mining	Rainfall: intensity and amount energy load
Cultivation: plowing, leveling, and land forming	Waste disposal: industrial and urban wastes and by-products	Wind: velocity direction
Farming/cropping systems: cropping intensity, grain crops vs. tree crops, pasture, and stocking rate	Acid rain: intensity and chemical agents	Temperature: maximum, minimum seasonal and diurnal fluctuations length aspect
Agricultural chemicals: fertilizers and pesticides	Nonagricultural land uses: urban development civil structures and mining	Terrain: slope gradient and length aspect Parent material: geological formation Vegetation: age and species composition

Fig. 4 Interdependence of soil degradation on biophysical and socioeconomic factors.
Source: From Lal & Stewart.^[5]

quantitatively.^[2] To do so is to delineate threshold values or critical limits of soil properties beyond which soil’s life-support processes are severely jeopardized. Important soil properties whose critical limits need to be defined are rooting depth, plant-available water capacity, soil organic matter content, soil structural attributes, capacity and intensity factors, and limiting levels of principal nutrients. These limits are not known and vary among soils, climates, farming systems, land uses, and management.

- 2. There is a problem with the methodology. There have been only few attempts to standardize the methodology and validate the estimates by ground truthing representative soils and ecoregions. Consequently, estimates of soil degradation by the same process vary widely because of the differences in methodology and criteria used.
- 3. Soil degradation is estimated on the basis of visual observations, reconnaissance surveys, and opinions

of regional/local organizations. It is rarely related to actual and potential productivity.

- 4. There is a problem with double accounting. The same soil prone to more than one degradative process may be counted as many times.
- 5. Productivity is affected by land use, inputs, improved technology, and management. Estimating productivity without considering of important technology and management processes leads to erroneous data.

CONCLUSION

Understanding principal processes, factors, and causes of soil degradation is an important prerequisite to our ability to reverse the degradative trends and to preserve a healthy state of global environment. Being a complex problem, it requires a systematic and coordinated effort to effectively address the major issues involved. These issues include: 1) obtaining reliable estimates of the land area affected by different soil degradative processes; 2) standardizing definitions and methods of assessment

Research, Jerusalem, Israel*

Abstract

Desertification is a persistent reduction of land's biological productivity of economic value—a terminal state of the land degradation process. Land degradation and desertification (LDD) can occur anywhere but the focus of this entry is on drylands, whose natural low productivity is water limited. LDD is a syndrome of interactive biophysical processes whose direct drivers are land resource overexploitation by land users. Underlying causes of LDD are economic, demographic, social, cultural, and political, operating across scales. About a quarter of global land is degraded and active LDD is ongoing. LDD is of concern—it is believed to contribute to poverty, migrations, refugees, and conflicts; it undermines global food security and the emissions from degraded lands exacerbate global climate change, which is projected to increase the contribution of drought to LDD and has already increased drying and a geographical expansion of some drylands. Some dryland communities demonstrate resilience to the underlying causes and take measures for avoiding LDD and the United Nations Convention to Combat Desertification is instrumental in assisting developing countries addressing their LDD.

INTRODUCTION

“Desertification” is a human-driven process, which impinges on a significant part of earth's natural capital, land, by reducing its productivity. Desertification is probably as old as the pastoral and farming livelihoods but has attracted attention only in the 20th century, such that as it turned into the new millennium, desertification has been ranked among the greatest contemporary environmental problems.^[1] Although literally the term links with deserts, desertification hardly occurs in deserts. Rather, desertification affects non-desert areas, all around the globe, and is of major concern, as it is a driver of poverty, mainly in the rural areas of the developing world, but at the same time puts at-risk food security at the global scale. This entry explains what desertification is and describes how it occurs, where, by whom, and why. It then elaborates on its implications to people across scales, from local to global. This is followed by scanning through the measures taken by people and the international community to address this threat to human survival and global sustainability. The entry closes with the effect of global climate change on desertification, now and in the future.

WHAT IS DESERTIFICATION?

Deserts—areas of poor vegetation cover and of the driest climate on earth—were molded by climatic processes, such as scarce rainfall and intense evaporation. These jointly constrain plant productivity such that much of the desert

appears lifeless. As the world's deserts were formed by natural climatic processes over long periods during which they have grown and shrunk, the term “desertification” can grammatically describe desert formation. However, the term was apparently coined first in a 1949 publication,^[2] not for describing a climate-driven outward spreading of deserts, but for a human-driven decline of land productivity to levels reminiscent to those of deserts, while climate remained a non-desert one. The term came into widespread international use only as of the 1970s, then being defined and redefined ever since. All definitions, however, related to a land attribute critical to all people, everywhere and always—the marketed biological products, food and fiber, which are derived from the land's biological productivity. Thus, desertification is best expressed by a persistent reduction, relative to the potential, of the land's biological productivity of an economic value.^[1,3]

DESERTIFICATION AND LAND DEGRADATION, DRYLANDS AND NON-DRYLANDS

The decline in biological productivity of economic value is driven by biophysical processes of “land degradation,” which can operate on lands used by people anywhere on earth but mostly affect lands whose productivity is constrained by water. Water is one of the raw materials required for the biological production process, but atmospheric carbon dioxide (CO₂) and soil minerals, as well as light. Each of these can limit productivity, even if all the others are available in abundance. Land degradation occurs in areas

of low water and high evaporation, thus making soil water the limiting factor. This water scarcity exists in all lands exposed to a potential annual evaporative loss that is at least about one and one-half times greater than the mean annual gain through rainfall. These are “drylands,” depending on their degree of aridity, they are classified into desert drylands (hyperarid and arid drylands) and non-desert ones (semiarid and dry subhumid drylands; Fig. 1).

The United Nations Convention to Combat Desertification (UNCCD) confined its mandate (to “combat desertification”) to degradation of drylands only, excluding the most arid ones, the hyperarid desert drylands. Also, the stakeholders of the UNCCD habitually use the two terms, “land degradation” and “desertification” interchangeably or jointly. However, there is an increasing tendency to address “land degradation” as a process, while regarding “desertification” as a terminal, extreme state of this process and to use both terms for processes impinging on biological productivity in non-dryland areas too.^[3,4] These tendencies have driven an increasing usage of an acronym for Land Degradation and Desertification, namely, LDD.

HOW LDD IS CAUSED?

Biological productivity depends on the land’s soil, which provides trees, forage and crop plants physical anchor, and raw materials for the production process. The loose and aerated texture of the soil is due to its organic matter that

binds the soil’s mineral particles together. The binding creates aggregates with air spaces between them that retain water in which the plant mineral nutrients are dissolved. This particulate texture of soil, however, makes it vulnerable to the mechanical force of wind, which blows away the soil’s fine components what often leaves sandy areas and dunes, and of rainwater, which carries soils away. These soil erosion processes reduce fertility as most nutrients are confined to the uppermost soil layers, which are directly exposed to the eroding forces. As the rate of soil formation is extremely slow, for all practical purposes soil is non-renewable and hence topsoil loss is one of the major causes of persistent productivity decline. It is plant cover that provides soil protection, by mitigating wind force and reducing the impact of raindrops that would otherwise destroy the delicate soil texture. Breakage of the aggregates results in soil crusting, leading to land surface sealing that reduces soil water absorption. Rather than infiltrating and enriching soil moisture, rainwater turns into surface runoff that erodes the soil or leaching away dissolved soil minerals and its organic compounds. These losses directly reduce fertility and indirectly reduce the water-holding capacity of the soil, what also slows down the soil microbial activity essential in nutrient recycling. Thus, due to soil erosion plants may lose their physical support as well as their production resources. Another major driver of declining productivity is soil salinization. Almost all types of water, including rainwater, contain some dissolved salts, which are left in the top soils after soil moisture evaporates or is transpired by the plants. This accumulated salinity reduces plants’ ability to suck moisture from the soil, and the resulting soil sodicity (predominance of sodium ion in soil moisture) limits water absorption by soils. To conclude, while climatically driven water scarcity makes dryland productivity low compared to most other lands,^[1] drylands are vulnerable to soil erosion and salinization (Fig. 2), the major physical and chemical processes, respectively, leading to LDD, whose ultimate expression is productivity loss.

WHO CAUSES LDD?

Depending on whether the biological products of economic value are derived directly from wild plants (e.g., woody plants used for timber and firewood and other edible wild species) or indirectly from free-ranging livestock feeding on wild plants or from cultivated crop plants; lands and their productivity are managed by their users through interventions expressed in natural resource exploitation rates, livestock stocking rates, and soil fertility levels. These interventions sustain people, societies, and their prosperity, yet they often pose potential threats to the land’s productivity, which could ultimately impinge on the land users themselves and on others. This is because while all productivity is derived from plants, their exploitative removal, either through grazing or harvesting, exposes the land to

Fig. 2 The dryland syndrome—climate-driven natural processes driving soil biophysical processes leading to inherent low productivity, to erosion vulnerability (solid arrows, two negative feedback loops), and to salinization vulnerability (broken arrows).

Source: Adapted from Safriel.^[5]

degradation processes once a threshold of plant cover is removed and/or one of regeneration relative to exploitation rate is crossed.

Regarding the pastoral livelihood, high livestock densities maintained throughout a long period reduce the overall soil protective cover, exploit vegetation faster than it can regenerate, and export nutrients (through selling livestock and their products) faster than their natural renewability. These encourage non-forage plants to dominate the range, promote encroachment of bushes that obstruct livestock foraging movement, and reduce soil physical resilience to livestock trampling, which compacts soil surface, reduces rainfall infiltration thus increasing risks of powerful surface runoff that erodes the soil and changes the local topography. Individually or combined, these processes lead to a persistent rangeland productivity loss (Fig. 3). As to the farming livelihood, long fallow periods expose the croplands to erosion forces, but in short fallow periods, a high number of crops cultivated each year and a large amount of nutrients exported in the harvested agricultural products, individually or combined, are of a potential to cross the threshold of land degradation. This is through nutrient loss that is faster than its renewability and a decline in soil organic matter, which reduces soil permeability, and the water-holding capacity leading to increased erosion vulnerability. Irrigation, used mainly in drylands for increasing the productivity of otherwise rainfed agriculture, has dramatically increased not only the economic productivity but also the soil salinity. Dryland water is scarce and hence not used for leaching soil salinity and when used, nutrients are leached too. Furthermore, much of dryland water is brackish, and irrigation systems devoid of drainage cause water logging, leading to further soil salinization. The irrigation-driven increased economic productivity amplifies nutrient

Fig. 3 Actions of land users that constitute the proximate, direct drivers (top boxes) of the LDD syndrome (bottom boxes) and their feedbacks and linkage (thick arrows), in each of the two prevailing dryland livelihoods.

export through harvest, which needs to be balanced by fertilizers. This combination of irrigation and fertilization could generate immediate economic gains, often succeeded by LDD (Fig. 3).

Practitioners of both livelihoods, but more often of the pastoral one, also exploit the woody plants of natural or planted woodlands and of rangelands, for timber and fuel wood, or remove all vegetation cover of woodlands or rangelands, to be replaced by expanding cultivation. These processes, too, expose large swaths of land to erosion processes and eventual LDD. To conclude, human land uses directed at increasing the inherently low dryland productivity of economic value are of a potential that is often materialized to bring about LDD. The persistent decline in productivity, rather than its aspired increase, attests to a preceding shift from grazing, cropping, and exploitation to overgrazing, overcropping, and overexploitation—activities of land users that constitute the direct, biophysical drivers of the LDD processes.^[6]

WHY LAND USERS CAUSE LDD?

It can be expected that land users are well adapted to their local environment and hence possess the knowledge for using their lands sustainably, i.e., without degrading it. As land degradation does occur in areas used by experienced users, factors beyond their control may be involved. Indeed, indirect drivers of change, or underlying causes of LDD that affect the direct, proximate causes that change non-degraded to a degraded land can be invoked (e.g., Fig. 3). These can be population (or demographic), economic, technological, policy and institutional, cultural, and political drivers.^[7] Each of these (Fig. 4) can affect the direct LDD biophysical drivers alone, jointly, linearly, or interactively, across different temporal and spatial scales.^[8]

Fig. 4 Underlying socioeconomic and policy indirect LDD drivers and their interactions.

Source: Adapted from Reynolds, Grainger, et al.^[8]

However, in spite of an increasing research and political interest in these LDD drivers, there is not enough field evidence, hence also agreement, regarding the role and relative significance of each of the variables that structure the network of pathways to LDD, and therefore the LDD “syndrome” is illustrated by paradigms that can be perceived as structured programs for further research. An “LDD paradigm” (Fig. 5) integrates elements of the Desertification Paradigm,^[9] the Dryland Livelihood Paradigm,^[10] and the Dryland Development Paradigm.^[11] Under this paradigm, LDD is driven by mutually interactive biophysical processes within the land’s “Ecological System” and by mutually interactive socioeconomic and policy processes within a “Human System,” integrated into an interactive “Human–Environment System” that oscillates between land’s sustainable use and LDD. The LDD paradigm attends the effect of LDD on human well-being at different spatial scales—effects that often further exacerbate rather than mitigate the LDD state. These are mainly poverty at the local scale, and migrations, refugees, conflicts, and foreign interventions at the regional and even global scales. In short, land users are driven to overexploit land, mostly by economic factors that in themselves can be driven by demographic variables, social and cultural factors, and by economic and social policies and political processes molded at diverse regional and global processes on which they have no control.

WHERE AND HOW MUCH LDD THERE IS?

As biological productivity expressed in market-traded products of economic value is regularly monitored a detected decline in the production of crops or in livestock-derived products can be used to delineate LDD-affected areas and quantify their spatial extent. However, the quantities of

Fig. 5 The LDD paradigm—interactions and feedback loops: Direct proximate LDD drivers (A) (detailed in Fig. 3), driven by underlying socioeconomic and policy drivers (B) (detailed in Fig. 4) generate the LDD syndrome (C) (detailed in Fig. 3); the reduced human well-being impinges on the direct drivers thus further exacerbating LDD (E); underlying indirect biophysical drivers also drive people to further exacerbate LDD (F) (detailed in Fig. 2); the locally affected human well-being (D) also has regional and global repercussions (G); and human well-being at all levels impinges on the underlying LDD drivers (H). Vertical arrows indicate the linear effects of variables from top to bottom of lists, while bullets indicate the independent effects of each variable.

marketable agricultural products per unit area do not necessarily reflect land productivity, as these much depend on the land users’ management decisions, driven mainly by economic considerations. Therefore, instead of monitoring marketed land products scientists turned to monitoring land and soil attributes serving as indicators of productivity. As different studies use different indicators and measurement methods, it is not surprising that five global assessments during the last decades resulted in LDD estimates ranging from 15% to 63% of global land and 4% to 74% of its subset of global drylands.^[12] A critical review of these studies suggested (with “medium certainty”) that 10–20% of the global drylands have been degraded by year 2000,^[9] while an earlier study qualified 12% of non-dryland as degraded.^[13] The latter study qualified 5.7% and 3.8% of Asian and African lands as degraded, respectively, and 1.9%, 1.7%, 1.2%, and 0.8% of lands in South America, Europe, North America, and Australasia as degraded, respectively, which combined to classify 15.1% of global land as degraded.^[14]

The development of frequent and accessible time series of earth monitoring from space enabled assessing not just the amount of degraded land but the rates of ongoing LDD. Satellite-born sensors of radiation reflected and emitted from the earth’s surface, and especially from its vegetation

cover, are used for following the course of biological productivity changes within given time periods. Most studies attend selected regions but one^[15] addresses the dynamics of biological productivity of vegetation cover at a global scale. This 23-year (1981–2003) analysis of remote sensing images revealed persistently declining overall productivity (i.e., not just the subset of direct economic value) at 24% of the global land, on which 1.5 billion people reside. It mainly occurred in Africa south of the equator, southeast Asia and South China, north-central Australia, the Argentinean Pampas, and swaths of the Siberian and North American taiga. The study also found that land degradation in China is more severe in forests than in croplands. However, measures taken to control the productivity–rainfall interaction need to be refined in making such assessment fully reliable.^[16] Nevertheless, the available studies demonstrate that as much as a quarter of the global land is already degraded, and active LDD is in force, which points at the vulnerability of non-degraded lands around the globe, especially in drylands.

WHY LDD IS OF CONCERN?

LDD reduces the capacity of earth to provide food; hence, it is of concern not only to the direct land users but also to humanity at large. Furthermore, even the LDD's local effect on the well-being of the direct land users is implicated with generating externalities of a global concern, as the local LDD-driven poverty leads to within-country, cross-boundary, and overseas migrations of refugees, which often trigger conflicts of variable severity and foreign and international interventions (Figs. 4 and 5). This component of the LDD paradigm is widely alluded to, though hard data on the causation and the dimension of each of these processes at the global scale are scarce. Regarding poverty, countries' statistics of poor rural land users do not distinguish between LDD-driven poverty and poverty not driven by LDD; it adds the poverty of land users with that of rural people who do not live off the land, as well as that of the country's dryland and non-dryland inhabitants. Thus, only localized statistics (e.g., 68–84% poverty in the drylands in northern Kenya that is higher than in other, non-dryland parts of the country) suggests a prevalence of poverty in drylands of developing countries and also has led to a rough estimate of about nearly one billion people in poor rural drylands.^[17] A direct, quantifiable linkage between poverty and LDD at the global scale is so far provided only by the observation that the poverty indicators—infant mortality and malnutrition of under-five-year-old children track the trajectory of desertification severity across the global aridity gradient (Fig. 6). Similar to the LDD–poverty nexus, there is no hard data on the linkage among poverty, migrations, refugees, and conflicts, and evidence for LDD being instrumental is circumstantial. Most cited are migrations following severe droughts, while only a few cases present a direct linkage, e.g., the Tambacuanda region of Senegal's

Fig. 6 Trends of LDD and poverty indicators across the aridity gradient of the global drylands.

Source: Adapted from Safriel.^[18]

1960s migrations driven by soil erosion-triggered decline of crop production—to the capital, other cities, other African countries, and Europe.^[19] Social scientists also disagree on the role of environmental degradation (LDD included) in generating conflicts and violence and concluded that empirical evidence is insufficient to demonstrate a tangible effect.^[20] However, comprehensive research of the Darfur conflict^[21] asserted that LDD in both croplands and rangelands has been one of the major factors in that crisis but it has been also intertwined with a range of other socioeconomic and political issues. Even if LDD does not always generate local poverty of regional and global repercussions, any local loss of land productivity undermines food security not only locally, but also at the global scale. It has been estimated that for feeding the global population by year 2050, 8.9 million km² of good cultivable land would be required, on top of the 15 million km² already under cultivation.^[22] However, only 4.4 million km² of cultivable land will be available.^[23] Therefore, LDD which practically converts cultivable to non-cultivable land could dramatically aggravate the already fragile global food security. LDD is of concern not only due to loss of crop and forage production but also due to loss of other benefits that people derive from the land, such as water regulation and purification, local climate amelioration, pollination, biodiversity conservation, and others. These benefits, called “ecosystem services,” are an expression of the land’s functionality as an ecological system. Adopting a holistic approach, LDD is increasingly described as a persistent, substantial reduction in a bundle of services provided to humans by cultivated, range, or natural ecosystems.^[1,24] The persistent decline in the provision of one of these dryland ecosystem services, carbon sequestration (the uptake of atmospheric CO₂ by plants and transforming it to plant biomass and litter) is of global concern, too. All dryland vegetation and all dryland soils store 14% and 20% of the

global organic carbon, respectively.^[9] LDD-associated soil erosion and loss of plant cover and plant productivity deplete this land's storage of organic carbon. This locally removed organic carbon is eventually oxidized and emitted back to the atmosphere, thus increasing atmospheric CO₂ concentration and exacerbating climate change, globally. Indeed, drylands' LDD-driven emissions are estimated to comprise about 4% of the total global emissions from all sources combined (in year 2000),^[11] and added LDD would further amplify global climate change.

Land degradation and desertification (LDD) data are of GLASOD,^[13] with the "low degradation" category excluded; data of infant mortality per 1000 births and percentage of hungry children under the age of 5, drylands of OECD countries excluded, are from the Millennium Ecosystem Assessment.^[9]

WHAT HAS BEEN DONE AND WHAT CAN BE DONE?

That most lands used in drylands are not yet affected by LDD suggests that drylands can be used sustainably. Many cases have been documented, mostly in East and West African drylands, in which rural communities adapted to rapid population growth, globalization, market development, and technological change and avoided LDD. These apparently detrimental changes triggered innovative actions: investments in more intensive yet sustainable land use, which helped reaping benefits of the enlarged market opportunity; exploitation of local bioclimatic and social comparative advantages; access to technologies that increased land and labor productivity faster than population growth; and improved access to growing markets.^[25] Avoiding LDD can be also achieved by adding income-generating "alternative" land-independent livelihoods like tourism and aquaculture,^[26] or generating supplementary income from seasonal migration to urban centers.^[19]

Nevertheless, it is developing countries that share most of the global drylands,^[9] as well as probably the most rural poverty and LDD risks. Noting these facts and being aware of the global threats of dryland LDD, the international community negotiated and adopted the UNCCD, with the intention of coordinating and promoting assistance of industrial (developed) to developing countries in addressing their LDD problems. Entering into force in 1996, the 195 country parties of the UNCCD together with the Secretariat and the subsidiary bodies of the Convention succeeded in raising awareness, encouraging knowledge and research, and promoting capacity-building and partnerships in projects on the ground, as well as installing mechanisms for assessing success. A major thrust of the international community is to drive the political process of setting a sustainable development goal—striving for Land Degradation Neutral World—and its associated target of achieving Zero Net Land Degradation (ZNLD) by 2030, initiated at the United

Nations Conference on Sustainable Development convened in June 2012 in Rio De Janeiro. The rationale behind this target is that completely halting further decline of the productive, non-degraded land within a relatively short time is unattainable. However, the amount of non-degraded land that becomes degraded within a time period can be offset by a similar amount of already degraded land, whose productivity is restored within the same time period. Once this offset is attained, the net rate of LDD is zero. Setting such goals and targets can help shape expectations and create the conditions for all stakeholders to assess progress and take appropriate action in addressing LDD.

As to reducing LDD for addressing the ZNLD target, "sustainable land management" (SLM) is widely prescribed. In practice, any land that supports the user does not lead LDD to qualify as SLM. More specifically, practices of land use need to adaptively maintain the resilience of the used ecosystems to all LDD drivers, such that the thresholds in ecosystem functions will not be crossed and the service provision will be sustained.^[27] Avoiding degradation may be easier and cheaper than restoring already degraded land but, as land is often degraded inadvertently while restoration is planned, its success prospects are relatively high. The first stage is removal of the LDD causes, to be followed by selecting from the rich literature of ecological restoration,^[28] the toolbox appropriate for the local state and the set restoration target.

DESERTIFICATION AND CLIMATE, AND CLIMATE CHANGE

Drylands are not only exposed to climate-driven water scarcity but also to high between-year variability. This includes relatively short periods (<5 years) during which rainfall and hence productivity remains far below the long-term average. These periods are termed "droughts," and since their associated productivity decline is reversible, this productivity decline does not qualify as desertification. It can be expected that a drought-driven productivity decline would persist after the drought terminate, provided that it has been severe and exceptionally long. Such events, if ever occurred, have not been reliably documented. On the other hand, drylands in which human-induced LDD processes have been already initiated are likely to be pushed by a drought to cross the desertification threshold, such that productivity decline would persist after the drought terminates. Such cases are rare, too. Even the reduced productivity during the Sahel droughts of 1968–1973 and 1982–1984 in the 20th century, which took a heavy toll on properties and lives and aroused the world's concern that culminated in adopting the UNCCD, was restored once the droughts terminated.^[29] Nevertheless, although droughts alone do not cause LDD, they do exacerbate LDD and its effect on human well-being, and hence droughts are listed among the underlying, indirect biophysical LDD drivers (Fig. 5). The role of drought in

desertification is laid out in the full name of the UNCCD—a convention “to combat desertification, in those countries experiencing serious droughts ...” and in its objective, that is not only to “combat desertification” but also to “mitigate the effects of droughts.”^[30] In spite of the difference between “combating” and “mitigating,” an emerging and widely used acronym for the UNCCD’s subject matter is Desertification, Land Degradation, and Drought, or DLDD.

Coining the DLDD acronym is partly justified given that the frequency of droughts and their severity is projected to increase, driven by the global warming and climate change. Indeed, climate change (and poverty) is projected to intensify desertification by 2050 in all the four Millennium Ecosystem Assessment’s scenarios of global governance.^[1] Climate change’s effect on global aridity is already evident. Comparison of the climatic conditions, precipitation, and temperatures that prevailed in 1931–1960 and used for setting the drylands’ boundaries, with those prevailing in the period of 1961–1990, demonstrated that the spatial extent of the African hyperarid and arid drylands increased by 51 and 3 million hectares, respectively, which comprise 1.7% and 0.1% of their area extent in 1931–1960, respectively. More significant is the “loss” of 25 million hectares of African non-drylands of 1931–1960 that turned into dry subhumid drylands during 1961–1990.^[31] Furthermore, rainfall decreases and evapotranspiration increases are projected to intensify this trend in many drylands by mid-century (IPCC 2008).^[32] To conclude, although LDD is driven by humans at the local scale, climate change, apparently human-driven, too, also leads to local productivity persistent decline, that is LDD, but one in which the local land users are not directly involved.

CONCLUSION

Desertification is a persistent reduction in land’s biological productivity of an economic value, as well as in other services provided by the land’s ecosystems. It is an extreme, terminal state of the land degradation process, and LDD can occur anywhere but the focus is on drylands; 40% of global land whose inherent low productivity is constrained by water. LDD comprises a syndrome of dynamically interactive biophysical processes, directly driven by land management practices of land users, themselves driven by underlying socioeconomic and policy interlinked processes that cross temporal and spatial scales, as well as by the inherent vulnerability of dryland soils to LDD, and by the effects of droughts.

Although the cumulative area of degraded land is only about a quarter of the globe’s productive land, the process is ongoing apparently at an increasing rate. LDD is therefore of global concern—the poverty it inflicts on the local land users is a source of migrations, refugees, and conflicts across boundaries and scales; the local loss of productive land risks the already fragile global food security. In addition, LDD and global climate changes are interlinked; climate

change increases dryness and hence LDD vulnerability, and LDD reduces the land’s carbon storage locally thus increasing emissions and warming, globally. The good news is that the UNCCD succeeded in raising awareness to the LDD plight, such that the international community seems ready to commit itself to significantly reducing further degradation and investing in restoring already degraded lands. Knowledge, institutions, and instruments are available, and the political will and resources need to be secured.

Desertification: Extent

Victor R. Squires

Adelaide University, Adelaide, South Australia, Australia

Abstract

Desertification is a global problem. The United Nations Environment Program estimates that about 35% of the earth's land surface and about 20% of its population are affected by it. Clearly, desertification is a major environmental and social problem. The problem is worse for heavily populated countries on the desert margins. The global overview of desertification provides a summary but recognition must be given to regional differences and impacts. A global summary of the kind presented in this entry is a useful first step to take when looking at a large-scale issue.

INTRODUCTION

Desertification, as a *concept*, is one of the most complex to consider objectively. The word desertification unfortunately conjures up images of advancing sand dunes, which is only part of the problem. There is a general acceptance of the term *desertification* to encompass a process of land degradation in drylands (those regions with a growing season of about 75–120 days per year) induced by climatic factors and human use. Fig. 1 shows the broad distribution of the world's drylands.

Whatever the definition, it is clear that large areas of the world's drylands are affected by land degradation and that this adversely affects the lives of about 1 billion people on almost every continent. To assess the global extent of desertification implies that there is universal acceptance of the term and that the monitoring and evaluation are somewhat uniform. Neither supposition is true. Until the decision by the United Nations Conference on Desertification,^[1] there was only broad agreement as to what was meant by it. It is only as signatories to the convention to combat desertification (CCD) have been preparing and implementing their respective action plans that are more accurate assessments which have been made of the status of desertification in each country. Prior to this, the maps and other documents produced by the United Nations through its various agencies were the product of expert panels who developed maps of the areas of potential desertification.^[2] Every inhabited continent has a problem with desertification, but in some, it is quite acute. Land degradation induced by human activities (anthropogenic) is believed to be lowering the productivity of at least one-fifth of the world's agricultural lands. Soil erosion from water and wind is a principal but by no means the only soil degrading process. Subhumid and semiarid areas in crops or pastures are particularly vulnerable to erosion.

Land degradation in such areas leads to desertification by definition. Anthropogenic land degradation, however, also affects large areas of arable land and pasture in humid regions as well.

Depending on how it is measured exactly,^[3] up to 75% of some continents are affected. The impacts are greatest in those regions with high population density and where the level of economic development is low; e.g., Australia is reported as having more than 75% of its land surface affected to a greater or lesser extent by desertification. Its low population density and the low level of dependence on these drier regions for its national prosperity mean that desertification is perceived as a lesser threat in Australia than in regions of comparable climate in the Indian subcontinent or in Africa.

ASSESSING THE EXTENT OF THE DESERTIFICATION PROBLEM

Desertification comprises two main types of degradation: vegetation degradation and soil degradation.

These can occur anywhere in dry areas and not just on desert fringes. Vegetation degradation involves a temporary or permanent reduction in the density, structure, species composition, or productivity of vegetation cover. It has been argued that degradation of vegetation should be given less weight in the assessment of desertification because there is clear evidence that most change in vegetation is reversible over reasonable timescales, whereas soil degradation is unlikely to occur within a human life span.

Desertification might be thought of as a situation where a landscape is stressed beyond its resilience. Most scientists would agree that, despite their apparent fragility, dryland ecological systems are quite resilient. The spatial and temporal variation in conditions means that

Fig. 1 Distribution of world's drylands.

coping mechanisms have developed to allow the system to continue in the face of adversity. Under the combined force of human-induced pressure and climatic forces, such as recurrent drought, major changes in soils and vegetation can occur. This is what has come to be recognized as desertification. This is what the CCD is designed to combat.

Desertification is a product of complex interactions between the social and economic systems (disease, poverty, hunger, and unreliable economy) and natural factors (drought, water erosion, soil salinization, degradation, and loss of vegetation cover). It is not surprising then that the criteria used to objectively assess the areal extent vary between regions. It is clear that a definition based purely on climatic indices does not give a true picture of the full extent of the problem.

No one has been able so far to monitor and document desertification and the resulting land cover change through reliable, verifiable, and repeated observation on a global, continental, regional, or even national scale. There is not full agreement on a single indicator of dryland degradation or an approach to assess and study desertification. Dryland degradation has many faces (driving forces as well as symptoms). It can only be assessed and understood through

an interdisciplinary study of the changing characteristics and integrated trends of a variety of biological, agricultural, physical, and socioeconomic indicators over a long time period and at a variety of spatial scales.

Because of the scale of mapping and the fact that most desertification occurs as a mosaic of small, often-isolated, areas, mapping defies the use of synoptic techniques such as remote sensing from Landsat and other satellites. Land cover/land use maps are being prepared by a number of countries, and on a global scale, land cover is being assessed by the analysis of satellite data. These may help to clarify and quantify the extent of desertification, especially where local input helps in verification and ground truthing.

The use of the low-resolution NOAA/Advanced Very High Resolution Radiometer satellite to generate a greenness index and to develop the normalized difference vegetation index might, on a broad scale, assist in monitoring change in plant cover and hence be an early warning of incipient change. But such change may only be a reflection of variability in space and time that characterizes the world's dryland regions. It is likely to be more useful in studies of drought and vegetation mapping. Its potential for use in desertification monitoring may be limited.^[3]

Table 1 Some common manifestations of desertification.

Economic manifestations	Ecological manifestations	Social manifestations
Economic loss in cash	Loss of diversity in terms of wildlife, plants and ecosystems	Migration of population off affected areas
Decreased crop yield	Loss of inland lakes	Rural poverty
Loss of farmland due to desertification	Loss of topsoil in terms of organic matter, N, P, and K plant nutrients	Influx of ecological refugees into urban areas
Loss of rangeland due to desertification	Decreased ground water level, increasing salinity of water	
Decreased grazing capacity in terms of the number of livestock	Increased frequency of sand storms and associated losses of human lives and livestock	
Abandoned farmland		
Abandoned rangeland		
Drifting sand affects railway lines and highways		
Increase in suspended load raises river height and increases flood problems		

The most immediately detectable changes can be quite misleading.

AREAL EXTENT OF DESERTIFICATION

The area affected by desertification in many developing countries is on the increase although the lack of sound baseline data makes any attempt at quantification difficult. Because a lot of desertification is characterized by a more dispersed, patch-like process of degradation, it is not amenable to remote sensing. It has long been recognized that

operational monitoring of patchy soil and vegetation degradation in dry areas is inherently difficult, even with medium-resolution satellite technology like Landsat MSS and those improved techniques are needed to make reliable monitoring and trend detection viable.

What is clear is that most of the more than 170 signatories to the CCD report growing concern about loss of productivity of their land in the face of rapid and continuing land degradation. The impacts are reflected in:

- loss of land resource through erosion and transportation by wind and water
- loss of productivity through land degradation
- eco-environmental change impacting on living conditions and health
- increased poverty and social instability in the rural hinterland
- flow-on impacts on cities and on industry
- effects on infrastructure and economic development

The principal manifestations of severe desertification are shown in [Table 1](#).

The United Nations Environment Program (UNEP)'s 1991^[4] estimate of the area of desertified land is 3.6 billion hectare, including 1 billion hectare of dryland suffering from soil degradation and another 2.6 billion hectare of rangeland with degraded vegetation.^[5] But an external review claimed that its accuracy was limited by considerable subjectivity (so observations were not repeatable); lack of resolution (so comparisons through time were not possible); and the use of point assessments which were unrepresentative of larger areas.^[6]

As indicated earlier, there are few objective measures of the areas of land affected by desertification. The most reliable maps are those published by UNEP in the revised edition of the *World Atlas of Desertification*.^[2]

Dr. Harold Dregne of Texas Tech University calculated the area of potential desertification ([Table 2](#)). Dregne determined the desertification status according to three factors taken as indicators, namely:

- changes in the composition of the vegetation
- extent of erosion; and
- the presence of soil salinity

Table 2 Distribution of the area of land susceptible to desertification (by bioclimatic zones).

Susceptibility to desertification	Bioclimatic zone (000's km ² %)						
	Arid	Semiarid	Subhumid				
Moderately	1144.5	6.6	12713.8	68.4	3345.6	23.4	
Highly	14585.8	82.5	2686.5	14.2		589.8	4.0
Very highly	1040.3	6.4	2157.5	12.4		173.5	1.3
Total	16770.6		17557.8		4108.9		

Source: Data from UNEP and other sources. Used with permission.

Table 3 Area of desertified lands by continent/region.

Degree of desertification	Africa	Asia	Australia	North America	South America	Europe	World total
Slight	12430	7980	2330	440	1340	—	24520
Moderate	1870	4480	3510	2720	1050	140	13770
Severe	3030	3210	520	1200	680	60	8700
Very severe	—	—	—	67	8	—	73
Total	17330	15670	6360	4427	3076	200	47063

Source: Data from UNEP, CCD, and other sources. Used with permission.

He singled out the following four degrees of desertification: slight, moderate, strong, and very strong. Strong desertification is an irreversible process when it is impossible to restore the land. This classification comprises mobile sand dunes, heavily salt-affected land, and badlands. In Dregne's opinion, such areas are not extensive, and their area is about 50,000 km².^[7]

The areas subject to severe desertification (Table 3) are in Africa, Asia, and South America and are mainly occupied by the developing countries. There are a number of drivers of change. These include rapid population growth, the availability of modern technologies for land conversion, as well as loss of traditional land use controls. Political and economic policy decisions, market and trade arrangements, the lack of environmental awareness, and the lack of capacity to combat the problem also contribute.

CONCLUSION

The evidence from many sources is that desertification is a global problem. UNEP estimates that about 35% of the earth's land surface and about 20% of its population are affected by it. Clearly, according to these figures and the data presented here, desertification is a major environmental and social problem. The problem is worse for heavily populated countries on the desert margins. When the extent of desertification is broken down according to major types of land use, we see that grazing land and rainfed cropping are most severely affected, each being desertified on over three-quarters of its area. Irrigated land suffers less so, with about one-fifth of the irrigated area in drylands affected by desertification (salinization and waterlogging).

The global overview of desertification provides a summary, but recognition must be given to regional differences and impacts. A global summary of the kind presented in this entry is a useful first step to take when looking at a large-scale issue. However, when working out a plan of action to combat desertification at the regional or local level, more detailed information needs to be gathered on the way desertification is happening and on its root causes. Such information can only be gathered by long-term monitoring of a particular area.

Desertification: Greenhouse Effect

Craig Idso

Center for the Study of Carbon Dioxide and Global Change, Tempe, Arizona, U.S.A.

Sherwood E. Idso

U.S. Water Conservation Laboratory, Phoenix, Arizona, U.S.A.

Abstract

What is the impact of the rise in the air's carbon dioxide (CO₂) concentration on the ecological stability of the world's deserts and the shrubs and grasslands that surround them? This question weighs heavily on the minds of many, as the nations of the earth debate the pros and cons of the prodigious CO₂ emissions produced by the burning of fossil fuels. On the downside, there is concern that more CO₂ in the air will exacerbate the atmosphere's natural greenhouse effect, producing changes in climate that lead to desertification. On the upside, the aerial fertilization effect of additional atmospheric CO₂ may enhance plant prowess, increasing plant water use efficiency and enabling vegetation to reclaim great tracts of desert. The challenge, therefore, is to determine the relative merits of these competing phenomena.

THE WORLD IN TRANSITION

Climatical Changes

Questions surrounding the climatical effects of the rise in the air's carbon dioxide (CO₂) content are contentious. There is evidence the earth has warmed significantly over the course of what is deemed the "Age of Fossil Fuels." Most of this warming occurred well before the largest increases in the air's CO₂ content were recorded, peaking in the 1930s. Thereafter, the atmospheric CO₂ concentration rose at a much greater rate than it had previously, while temperatures stagnated before staging a hotly contested comeback in the 1980s and 1990s—a comeback more virtual than real. It is also possible that the atmospheric warming in the late 19th and early 20th centuries was nothing more than a natural recovery from the global chill of the Little Ice Age. Hence, although many scientists believe there has been a discernable human influence on the global climate of the 20th century, other scientists take serious issue with that contention.

Biological Changes

Climatical effects in the biological arena are also complicated, but not so much that certain facts cannot be used to draw some broad conclusions. CO₂, e.g., is one of two main raw materials (the other being water) used by plants to produce the organic matter from which they construct their tissues. Thus, increasing the air's CO₂ content typically enables plants to grow better, as has been demonstrated in literally thousands of laboratory and field experiments.^[1]

In addition, the higher concentrations of atmospheric CO₂ cause many plants to reduce the apertures of the small pores in their leaves, through which water vapor escapes to the air. Consequently, with more biomass production per unit of water lost, plant water use efficiency is significantly enhanced. In fact, it approximately doubles with a doubling of the air's CO₂ content,^[2] allowing many species of plants to grow and reproduce where it had been too dry for them previously. Furthermore, the enhanced degree of ground cover resulting from this phenomenon reduces the magnitude of soil erosion caused by the ravages of wind and rain. And with greater plant growth, both aboveground and belowground, there are significant increases in the amounts of organic matter that enter the soil. That matter enhances the soil's ability to sustain the more productive shrub and grassland ecosystems that come into being via this process of reverse desertification.

Although supported by a plethora of scientific studies, this scenario of vegetative transformation has been challenged on the assumption that resource limitations and environmental stresses encountered in nature might overpower the ability of atmospheric CO₂ enrichment to significantly enhance the vitality of plants. However, in a massive literature review designed to investigate this question, it was found that the percentage increase in plant growth produced by an increase in atmospheric CO₂ is generally not reduced by less-than-optimal levels of light, water, or nutrients or by high temperatures, salinity, or gaseous air pollution.^[3] In fact, the data demonstrate that the relative growth-enhancing effects of atmospheric CO₂ enrichment are typically the greatest when resource limitations and environmental stresses are most severe.

Greening of the Earth Hypothesis

In light of these observations, there is reason to believe that the historical trend in the air's CO₂ concentration, which rose from a value of 280 parts per million (ppm) at the start of the 19th century to 370 ppm at the turn of the millennium, may already be producing an ubiquitous "greening" of the earth. This is especially true for bushes, shrubs, and trees since woody plants are typically more positively affected by increases in the air's CO₂ content than herbaceous plants.^[4] Consequently, the most readily documented aspect of this biological transformation should be seen in the spreading of woody vegetation onto grasslands.

WOODY PLANT RANGE EXPANSIONS

From Prehistory to Industrial Revolution

The savannas, grasslands, and deserts of the American Southwest and the Southern Great Plains got their start approximately 25 million years ago. About that time, the climate began to dry, and it continued to become more arid, particularly over the past 15 millennia. But when the engines of the Industrial Revolution began to pump CO₂ into the air at rates that exceeded natural geological processes, things began to change. As early as 1844, in fact, a trader from Santa Fe, New Mexico wrote in his memoirs^[5] "there are parts of the southwest now thickly set with trees of good size, that, within the remembrance of the oldest inhabitants, were as naked as the prairie plains." He summarized the situation by saying "we are now witnessing the encroachment of timber upon the prairies." And in surveying the land a century later, Malin^[6] would verify that trader's prescience by referring to the ecosystem it supported as a "tangled jungle."

Modern Studies

An especially good history of the vegetative transformation of the American Southwest was developed by Blackburn and Tueller^[7] from a study of the growth rings of juniper and pinyon communities in east-central Nevada, where they determined that juniper began expanding its coverage of the land well before 1800, with more rapid increases in the densities and sizes of both species occurring subsequent to that time. But just as the rise in the air's CO₂ content developed most dramatically in the 20th century, the most remarkable increases in the presence and abundance of trees at these sites manifest themselves after 1920.

A parallel example involving other woody species has been documented on the Jornada Experimental Range in New Mexico.^[8] When surveyed by the U.S. Land Office in 1858, no shrubs were evident on 60% of the land, and only 5% of the range contained what

could be described as dense stands of brush. However, 105 years later, none of the area was free of woody plants, and 73% of it was dominated by thick stands of mesquite and creosote. Texas, too, had been thus transformed. By 1963, 88 million acres of former grasslands had been replaced by brush and shrubs. By 1982, the figure had risen to 105 million acres (Figs. 1 and 2).

In a comprehensive review of this subject, Idso^[8] assembled many examples of woody-plant range expansions onto grasslands, citing studies conducted in California, Idaho, Kansas, Missouri, Montana, Nebraska, North Dakota, Oklahoma, Oregon, South Dakota, and a number of New England states. He also cited examples of the same phenomenon in South America, Europe, Asia, Africa, Australia, and New Zealand, augmenting this evidence with equally numerous and widespread reports of ever-accelerating woody-plant growth-rate increases.

Although a number of different hypotheses have been proposed to account for this vegetative transformation of the planet, many of which play significant roles in specific locations and circumstances, the ubiquitous nature of the phenomenon argues strongly for a single worldwide

Fig. 1 Photographs of the U.S.-Mexico border just east of Sasabe, Arizona. (A) Taken in 1893 by D.R. Payne: the area was devoid of shrubs. (B) Same areas, taken in 1984 by R.R. Humphrey, were dominated by velvet mesquite, ocotillo, velvet-pod mimosa, snakeweed, and burroweed.

Source: From Knapp & Soule.^[10]

forcing factor that dominates the effects of most other influences. The rise in the air's CO₂ concentration is the only phenomenon that would appear to meet this global-scale criterion.

CONCLUSION

What does the future hold? It will probably be more of the same. There are no signs that humanity's appetite for fossil-fueled energy will abate any time soon. Neither are there any indications the nations of the earth will be able to reverse this trend by regulatory or legislative fiat. Therefore, if we do not completely cover the globe with concrete and asphalt before the Age of Fossil Fuels ends, we will probably see woody plants continue their invasion of

grasslands, while grasslands intensify their assault upon the world's deserts.

With respect to global warming, it's anybody's guess. Even if it does occur, CO₂-induced increases in plant water use efficiency (a doubling for a doubling of atmospheric CO₂) and plant thermal tolerance (a 5°C increase in optimum growing temperature for a doubling of CO₂) should enable earth's ecosystems to keep on responding as they have over the 19th and 20th centuries. Thus, the greening of the earth should continue increasing vegetative productivity, the biomass of higher food-chain trophic levels, and ecosystem biodiversity concomitantly.^[11]

Desertification: Humid Environment in Iceland

Andres Arnalds

Soil Conservation Service, Hella, Iceland

Abstract

The term “desert” can have many different meanings. The scale of ecosystem disturbance in Iceland, where barren deserts have replaced vegetation and thick soils in many areas regardless of ample precipitation, demonstrates the global nature of this severe environmental problem. The world’s forests and woodlands are being reduced at an alarming rate in many parts of the world, and large areas are being overgrazed. The weakening of the vegetative cover can lead to a chain of ecosystem disturbances reducing further the resilience of the ecosystems toward further degradation. If prolonged, this can lead to desertification in a wide range of moisture regimes, as demonstrated by the Icelandic experience described in this entry.

INTRODUCTION

Desertification has wide-ranging consequences on a global scale. However, this term has generally been associated with or even confined to “land degradation in arid, semi-arid, and dry subhumid areas” (United Nations Convention to Combat Desertification, Article 1). Such definitions ignore the effects of natural or anthropogenic disturbances leading to ecosystem disturbances of functional equivalence in more humid environments or even high rainfall areas.^[1] Narrow definitions of “desertification” exclude other cases of severe degradation and may hinder progress in research, management, and policy development for mitigation of this immense environmental problem.^[2]

OVERVIEW

The history of vegetation and soils in Iceland since settlement of the island around 874 A.D. demonstrates clearly how the processes of desertification can render fertile ecosystems into barren wastelands, i.e., deserts, in a humid environment. During this time, Iceland may have lost about 96% of the original tree cover and about 50% of the vegetation. Land use interacting with natural disturbances led to catastrophic soil erosion that has devastated large parts of the Icelandic ecosystems.

More than 37% of Iceland is classified as barren deserts.^[3] In addition are other eroded areas and large damaged areas with limited plant production. The desert soils are infertile and generally have 0.5–5% vegetation cover, and plant succession may be considered primary. Botanical composition of remaining vegetation in many areas is characterized by unpalatable plant species that heavy grazing has given competitive advantage. Desertification continues to be a major threat to Iceland’s natural resources.

Such large-scale ecosystem disturbances greatly affect hydrological attributes such as infiltration rates, soil water storage capacity, precipitation characteristics, and rain use efficiency.^[4] Growing conditions for vegetation thus can change from mesic to xeric and from fertile to infertile regardless of precipitation, as evidenced by desertification of the humid environment in Iceland. Here, the perspective of van der Leeuw^[5] will be followed, namely, “to view desertification as a special case of very heavy and large-scale degradation, and look at the wider range of processes rather than focus on desertification.”

ICELAND—A WARM ISLAND WITH A COLD NAME

The Viking settlers who came to Iceland 1100 years ago (about 874 A.D.) saw a fertile land. Vegetation may have covered more than 60% of the country, and woodlands, mainly birch (*Betula pubescens*), covered at least 25% of the land area^[6] or even 40%.^[7] Deserts covered only 5000–15,000 km².^[2]

This vegetation had evolved under a relative warm regime, which continued through the first two centuries of settlement. The “icy” part of the name Iceland derives from icebergs from the north that Vikings saw drifting in one of the western fjords.^[1]

Climate and Soils

Iceland is in the subarctic belt, touching the Arctic Circle in the north. A branch of the warm Gulf Stream nearly encircles this 103,000 km² large island. The climate is maritime cold temperate in the lowlands to subarctic in the highlands. The winds are frequent and strong, mainly from the southeast and north. Annual rainfall is highly

variable, from 400 mm in the rain shadow north of the Vatnajökull Glacier to 3500 mm at the south coast.

Iceland is a young country in geologic terms, and there may be, on the average, one eruption every 5 years. The soils in most parts of Iceland are Andosols that draw their major characteristics from their volcanic parent material.^[8,9] Icelandic soils are also influenced by steady flux of Aeolian materials originating from desert wind erosion areas.

A Green Island—How Do We Know?

The extent and composition of vegetation in Iceland bear little resemblance to what it was historically. The ecosystem degeneration and desertification following settlement have been so extensive and spectacular. Iceland is not as fertile and hospitable to its inhabitants as it could be.

Arnalds^[10,11] summarizes some of the various sources that can be used to reconstruct the vegetation of the past and trace some of the major changes in cover and composition through the centuries. To mention just a few, the settlement time Sagas, written about 200 years after the episodes, refer in many cases to the woodlands of the past. Pollen studies, linked to the use of ash layers for dating, reveal sharp changes in botanical composition after settlement, especially the disappearance of birch from many lowland areas.

Historical records are a good source for comparison of past and existing land condition. A description of all farms in Iceland from beginning of the 18th century indicates fertile land in many areas that are severely degraded or barren deserts. Many old site or farm names, such as “Sko-gar” (woods), indicate lush vegetation in desertified areas, and the woodland word “holt” means a barren or infertile hill. Remnants of pits where charcoal was made out of birch, and other land use indicators, also tell a sad story of land degradation (Fig. 1).

Such information about changes in land health is important as one of the tools for setting goals for restoration of damaged land in Iceland. It is also a sharp reminder on the potential consequences of long-term unsustainable land use in a sensitive environment.

DESERTIFICATION IN ICELAND

The vegetative cover provided good protection for fragile volcanic soils. With the settlement, a delicate balance between forces of nature and vulnerable vegetation was disrupted.^[10,12] Subsequent soil erosion has devastated large parts of the ecosystem, reducing vegetative cover from about 60% to 30%. Trees cover only 1% of the land area.

Causes and Consequences

The initial causes of soil erosion in Iceland vary from place to place. However, the interaction of livestock grazing with weak soil structure, harsh climate, and volcanic eruptions is considered to be the main reason for the great ecosystem disturbance. Climatic fluctuations have also sped up this process, reducing further the ability of the vegetation to meet the relentless pressure of man and livestock. The importance of timescale and rare events, such as cold spells, volcanic eruptions, and periods of excessive tree clearing or overgrazing, as triggers of disturbance and destruction should be stressed in the interpretation of the degradation processes and history.

The initial impact of settlement was both immense and had long-lasting consequences. There are indications that the settlers brought with them cultivation techniques from their countries, mainly Norway. Vast areas of woodlands may initially have been burned to make space for pastures and cropland or to make nutrients stored in the woods available for crop and pasture plants. The birch and later shrubs were also extensively cut for fuel, and wildfires damaged many areas. Livestock grazing further changed botanical composition, reduced stability of the ecosystems, and interfered with vegetation recovery after weakening by other land uses and natural disturbances (Fig. 2).

A Vicious Cycle

While the birch woodlands were extensive, they sheltered sensitive soils from the natural forces. Woodlands have relatively strong resilience toward disturbance and recover quickly after limited disturbance, such as landslides, if grazing does not hamper regeneration.^[13] The woodlands

Fig. 1 Desertification in Iceland, leaving the naked glacial pavement behind. (A) Encircled by stones in the foreground, and visible for a short time while the soil is disappearing, is the bottom of a pit where charcoal was made out of birch trees. (B) Same place 16 years later.

Fig. 2 Unsustainable grazing is one of the interacting factors causing desertification in Iceland.

had a key role in stabilizing soils on hill slopes, which are generally in very poor condition. Active and severe soil erosion is on about 6000 km² of hill-type land. Many other slopes are devoid of vegetation, including stony scree slopes on about 5000 km².^[14]

Farms extended to relatively high elevations during the first centuries of settlement, reflecting good condition of the inland areas. The highlands were also used for sheep grazing from lower elevation farms. Many of highland farms had been abandoned around year 1100; critical thresholds in land health had been exceeded, and the climate was gradually getting colder. A vicious cycle had been initiated. Ecosystem stability had been reduced and both cold spells and ash from volcanic eruptions had ever-increasing impact on remaining vegetation and soils.

Following the initial impact of settlement, woodland destruction, livestock grazing, and environmental events continued to interact leading to damaged ecosystems or total loss of vegetation cover in large parts of Iceland. The rate of erosion may have been highest in the late 19th century and the first decade of the 20th century. The climate was unfavorable, with frequent cold spells. Iceland, then a Danish colony, gained independence of trade in 1885, and high grazing intensities following new markets for sheep wool and meat led to a period of massive ecosystem degeneration in many areas. Gísladóttir^[15] gives details of such marked related environmental changes in an area in south-west Iceland during the last part of the 19th century. The rapid ecosystem destruction was widespread, and in North and South Iceland, many kilometer-wide sand fronts were destroying vegetated areas, often at a rate of 200–400 m in a year, until the mid-20th century.

Pressure on dwindling sources for fuel wood kept rising until the late 19th century. Especially, there was a high demand for charcoal from birch to whet the sieges used for cutting hay, which had to be done by heating. A new type of siege brought initially to Iceland from Scotland in 1876 reduced demand for charcoal and may have saved many of the woodland remnants from total destruction.

With access to machinery and fertilizers in the 1950s, Icelandic farmers could produce more hay for winterfeeding, and livestock numbers rose rapidly. This led to a new period of overgrazing, until market forces and reduced

(C)

Fig. 3 The process of desertification in Iceland. (A) Birch (*Betula pubescens*) and willows protected sensitive soils. (B) With the destruction of the woodland cover, bare ground patches began to form, destabilizing the ecosystems and increasingly subjecting the sites to wind and water erosion. (C) Deserts characterized by glacial till, lava, and sandy surfaces have replaced fertile ecosystems in large parts of Iceland. This area was birch woodland about 400 years ago.

governmental subsidies in the early 1990s eventually led to 50% reduction in sheep numbers.

Stages of Desertification

The ecosystem changes and consequent desertification of Icelandic landscapes are likely to have followed stepwise degradation and desertification pathways as described by a conceptual model outlined by Aradottir et al.^[16] and further adapted by Archer and Stokes.^[1] Continuous cover of birch, willows, grasses, and forbs (State I) shifts to less-productive heath land (State II). Spots of erosion begin to form with continued interaction of anthropogenic and human disturbances (State III) gradually increasing the area of exposed soil. Erosion fronts (“rofabards”) form^[17] and soil and sand begin to encroach upon and weaken remaining vegetation (States III and IV). Remnants of vegetation and soils gradually disappear leaving glacial till or sandy surfaces behind (States V and VI). This desertification process is further shown in Fig. 3.

The cost of restoration associated with degradation increases rapidly within Stages III–V and becomes almost prohibitive in Stage VI (Fig. 3C), where nutrients, seed sources, etc. have been completely lost.^[16] For further elaboration, see also the work of Tongway and Hindley.^[18]

THE NATURE AND EXTENT OF SOIL EROSION AND DESERTIFICATION

Desertification continues to be a major threat to Iceland’s natural resources. A national assessment of soil erosion and desertification at a scale 1:100,000 was conducted over the period of 1991–1996.^[14] It is based on classification of

Table 1 Division of land in Iceland according to erosion classes.

Erosion class	Area (km ²)	Percentage of whole
0 No erosion	4,148	4
1 Little erosion	7,466	7.3
2 Slight erosion	26,698	26
3 Considerable erosion	23,106	22.5
4 Severe erosion	11,322	11
5 Extremely severe erosion	6,375	6.2
Mountains	9,794	9.5
Glaciers	11,361	11.1
Rivers and lakes	1,436	1.4
Unmapped	1,010	1
Total	102,716	100

Source: From Arnalds, Thorarinsdottir, et al.^[14]

erosion forms that can be identified on the landscape. The survey indicates that 40% of Iceland is experiencing serious soil erosion (Table 1; Fig. 4). Areas with high mountains, glaciers, rivers, and lakes were excluded from the overall assessment of land.

Soil erosion in Iceland is characterized by two overall mechanisms. The first is sand encroachment, where sand buries vegetated areas resulting in bare sandy deserts. The second involves mainly water and wind, which results in the removal of rich Andosol soils.

Sandy deserts with active Aeolian processes characterize nearly 22,000 km² or about 21% of the total area of Iceland.^[3] In large parts of the Icelandic highlands (about 13,000 km²), sand has drifted over the old gravel surface left by the Pleistocene glacier. A large part of

Fig. 4 Serious soil erosion characterizes 40% of Iceland, indicated here by the yellow (considerable), brown (severe), and red (extremely severe erosion) colors.

Source: From Arnalds, Thorarinsdottir, et al.^[14]

these areas were previously covered with 50–200 cm thick Andosols.

Erosion spots, openings in the vegetation with active erosion, are common on 27% of Iceland. Such erosion is mostly found in areas with low intensity erosion, Classes 1 and 2 (Table 1), but commonly leads to more severe erosion such as the formation of erosion fronts, the “rofabard.”

The “rofabard” is one of the most striking erosion features in Iceland. These are erosion escarpments where vegetated Andosols are being truncated from the surface and barren desert is left behind (Fig. 1). This form of erosion is prominent on about 20% of the area of Iceland and is a major environmental problem. Other forms of soil erosion are also active in destroying the Icelandic ecosystems.^[14]

Other common erosion forms are solifluction, landslides, gullies, soil movement on gravel flats (eroded land), and scree (for further, see the work of Arnalds et al.).^[14]

CONCLUSION

The term “desert” can have many different meanings. The term desertification thus may be regarded as a vague concept, as discussed by Arnalds^[2] in his appeal for a broader perspective on this global issue.

The scale of ecosystem disturbance in Iceland, where barren deserts have replaced vegetation and thick soils in many areas regardless of ample precipitation, demonstrates the global nature of this severe environmental problem.^[19] In Icelandic, the word “eyðimörk” is commonly used to describe the barren areas of the arid parts of the world, the “deserts.” It has two parts: “eyði,” which means empty or deserted and “mörk,” which is an old term for woodland. This word thus has its roots in the most severe environmental problem of Iceland, the conversion of woodlands to barren landscapes. The word “auðn,” which means empty or deserted, is commonly used to describe large barren landscapes in Iceland.

The world’s forests and woodlands are being reduced at an alarming rate in many parts of the world, and large areas are being overgrazed. The weakening of the vegetative cover can lead to a chain of ecosystem disturbances reducing further the resilience of the ecosystems toward further degradation. If prolonged, this can lead to desertification in a wide range of moisture regimes, as demonstrated by the Icelandic experience described here.

Desertification: Impact

David A. Mouat

Division of Earth and Ecosystem Sciences, Desert Research Institute, Reno, Nevada, U.S.A.

Judith Lancaster

Desert Research Institute, Reno, Nevada, U.S.A.

Abstract

Desertification's impacts on landscapes, biodiversity, and human populations are moderately well documented, and there are numerous suites of indicators in use for assessment and monitoring. Studies of the actual processes involved are valuable, particularly in areas that are marginal for desertification susceptibility, and are contributing to our understanding and therefore to our ability to meaningfully intervene to reduce or mitigate the effects of desertification on both the environment and human populations. Desertification is a phenomenon that will not disappear as a result of human intervention but may be reduced in severity or extent by a strategy including increasing the understanding of processes involved, monitoring, and investigating alternative management options.

INTRODUCTION

The United Nations (UN) defines desertification as follows: "Land degradation in arid, semi-arid and dry sub-humid areas resulting from various factors, including climatic variations and human activities."^[1] These dryland regions comprise 41% of the global land area, or 6150 million ha,^[2] and are present in every continent. Hyperarid regions are almost rainless, natural deserts, and not susceptible to desertification processes. Areas of concern are those that are desertified, that are at risk for increases or acceleration of desertification processes, and that are on the threshold of change but where sustainable human life is still possible.

Economic and political factors have changed the patterns and strategies of human occupation of dryland regions, where previous lifestyles of transhumance or nomadism and minimal involvement in a market economy permitted human occupation of arid and semiarid areas even in times of drought, without causing ecosystem stress.

MANIFESTATIONS OF THE DESERTIFICATION PROCESS

Dryland ecosystems are fragile, highly vulnerable to natural climatic fluctuations, and susceptible to desertification. Desertification impacts not only human populations and their livelihood but also the landscape—namely vegetation, soils, and hydrology—as well as insect, animal, and bird populations and biodiversity as a whole. Dryland soils are particularly at risk—their low levels of biological activity, organic matter, and aggregate stability can easily result in a

breakdown or decline of soil structure, accelerated soil erosion, reduction in moisture retention, and increase in surface runoff.^[3] Reduction in plant cover will exacerbate these processes, leading to a change of scale in the spatial distribution of soil resources,^[4] an increasingly "patchy" landscape, and a decline in sustainability that is difficult or impossible to reverse.^[5]

Dryland vegetation communities include grassland, shrubland, woodland, savanna, and steppe (Fig. 1) and vary according to climatic, edaphic, hydrologic, and anthropogenic factors.^[3] Change in vegetation community structure and reduction in cover may be a catalyst for desertification processes.^[6] A shift from grassland-dominated to shrub-dominated rangeland seems to be ubiquitous^[7,8] and is generally associated with increased soil runoff. The main causes of this vegetation change seem to be grazing, fencing, and alterations to the natural fire regime, in association with climatic variability.^[9]

The *World Atlas of Desertification*^[10] suggests that overgrazing, agricultural practices, the overexploitation of vegetation, and deforestation are the four most significant causes of soil degradation although bioindustry plays a locally important role in some countries. Soil degradation may result from displacement (by wind and water erosion) or internal deterioration by chemical or physical variables.^[11] Erosion of soil by water results in loss of topsoil as well as changes to the landscape such as gully and rilling. Loss of topsoil has an impact on both natural vegetation and cultivated crops^[12] and is the dominant erosion process in Africa.^[10] Wind erosion is most severe in areas that have been disturbed by human activity—e.g., by grazing pressure that reduces plant cover. Chemical

Fig. 1 Global distribution of vegetation communities.

Source: From Williams & Balling.^[3]

deterioration can be divided into the following three classes: a loss of nutrients, salinization, and acidification.^[10] A change in soil nutrients and a patchy distribution of nutrients at the landscape scale is a consequence of desertification^[5] and in some cases may be partially due to erosion of fine particles by wind and water.^[13] Physical changes in soil structure result from compaction, crusting, and waterlogging and—like salinization and acidification—are exacerbated by pressure of human land use and widespread irrigation.^[10]

Desertification is linked to poverty^[12,14] and tends to result in out-migration, initially of young people and men. This changes family structure and places burdens and constraints on the women, children, and old people remaining in the settlements—which in turn changes the patterns of land use and may exacerbate desertification.^[12] Loss of human dignity is perhaps the most insidious consequence of the desertification process—it is difficult to measure and difficult to reverse.

Measurement of the extent and severity of desertification has been an ongoing process since the 1930s and is well documented in many countries. However, in order to comply with UN treaties, management plans must be developed and implemented, education programs initiated, and local communities involved in decision-making. To do this

effectively, it is necessary to identify the areas that will most benefit from intervention and where desertification processes may be stabilized or reversed. International conferences addressing these issues were held in Tucson, Arizona, U.S.A., in 1994 and 1997^[15,16] at which indicators of desertification were much discussed.

INDICATORS OF DESERTIFICATION

Although some indicators may be relevant universally,^[17] a standardized list of indicators is not possible as the climatic, geographic, and anthropomorphic conditions of desertification are variable, as are technology, human, and financial resources. Most indicators tend to be of a “snapshot” nature that provide measures of condition and trend and a measure of what is “normal” only when compared in time and space. Process-based studies in semiarid and arid ecosystems that appear to be structurally and functionally intact^[18] may provide baseline data on the expected and inherent variability of systems, to permit the establishment of thresholds indicative of irreversible change.^[19]

Reporting on environmental indicators for the land, to meet Australia’s UN obligations, Hamblin^[20] selected

indicators that would distinguish between anthropogenic interventions and natural causes and recommended “key indicators” of condition, pressure, and response that would describe trend and impact on the environment. The indicators are grouped by process in relation to change in erosion, habitat, hydrology, biota, nutrients, and pollution.

The 1994 International Desertification Conference in Arizona identified nutrient availability, water budget, energy balance, and biological diversity as key ecosystem processes affected by desertification which apply across international boundaries and again recommended indicators that were grouped by process—in this case, nutrient availability, water budget, energy balance, and biological diversity. Of the total 28 recommended indicators, the following may be the most significant:

1. Infiltration, both under and between plants;
2. Cover type and distribution;
3. Erosion as indicated by rills, gullies, pedestalling, litter movement, flow patterns, and fetch length;
4. Depth to water table;
5. Normalized Difference Vegetation Index as a measure of greenness;
6. Surface temperature; and
7. Ratio of native to exotic species for flora and fauna.

There is a paucity of demographic or socioeconomic indicators in this list. Of the numerous indicators of desertification in general use, those concerning socioeconomic factors are the least developed, and there is a disconnect in many areas between the communities affected by desertification processes, the scientists conducting research, and policy-makers and managers.^[21] The disconnect between communities, researchers, and policy-makers has been a subject of concern in South Africa and Namibia for some time and has been addressed by several projects.^[22–24] The Karoo veld (rangeland) assessment handbook produced by Milton and Dean^[25] is a successful example of orienting scientific data and their interpretation to a specific non-science audience.

Soil is variable and complex, and the methods for assessing its condition are slow, tedious, and expensive; to compound the issue, differences in soil type may be mistaken for differences in soil condition.^[26] Also targeted to ranchers and managers, Tongway’s rangeland soil condition assessment handbook^[27] proposes an approach to assess the soil condition based on recognizing and classifying the processes related to erosion, infiltration, and nutrient cycling.

The world’s drylands provide critical habitats for migratory birds, and other wildlife,^[12] and the maintenance of biodiversity in arid and semiarid areas is a major concern. Measures of floral, faunal, and avian diversity and reproductive success must be included in the list of indicators used to assess and monitor the status and extent of desertification. However, like demographic indicators, those

involving biodiversity can be difficult to define, measure, and analyze and are frequently site specific. They may, however, provide the elusive “early warning” of a susceptibility for desertification that researchers and managers are seeking.

TECHNOLOGY, MEASUREMENT, AND ANALYSIS

The field data needed for desertification assessment and monitoring, such as soils and vegetation measurements, are typically collected at the plot scale, and many researchers, managers, and policy-makers have questioned the use of remote sensing because it provides a generalized measurement at scales of tens of meters to kilometers. However, there are numerous remote-sensing systems, operating at different spectral, spatial, temporal, and radiometric scales. The latest in the Earth Observing System series of missions launched in December 1999 carried new sensors, two of which are the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) and the Moderate Resolution Imaging Spectrometer. The ASTER mission objectives focus on understanding the earth as a system and the construction of models of earth’s global dynamics—including desertification.^[28]

The long-term perspective critical to desertification assessment is also an essential component of the evaluation of future management options and the development of remediation, land use, and management plans. A newly developed technique, i.e., alternative futures assessment, models potential changes to the landscape in a geographic information system (GIS) over several timescales, including projections for population growth. Models for basic environmental processes are then operated on the results of the change scenarios to show cumulative effects on the system as a whole.^[29] Workshops and questionnaires are used to ascertain current and future attributes of the area that are considered by stakeholders the most desirable, to identify plausible change scenarios, and to evaluate the results.

Long-term ecological studies at plot, regional and local scales, remote-sensing data, GIS, and alternative futures assessments are components of an integrated assessment, monitoring, and management strategy that is evolving in response to the need for greater interaction and communication between scientists, managers, and communities. This is a global concern, and the following case study for Southeastern Arizona discusses research in the context of a strategy that involves local communities, landowners, and managers in the decision-making process.

CASE STUDY—THE SAN PEDRO RIVER BASIN

The San Pedro River rises in Mexico and flows north through the semiarid shrub steppe of Southeastern Arizona. The Bureau of Land Management (U.S. Department of

Interior) manages the San Pedro Riparian National Conservation Area immediately bordering the river, where there is one of the highest animal biodiversity totals in North America. Vegetation change, especially the deterioration of grasslands due in part to grazing and the suppression of fire, has been a concern in the area for some years.^[30] This change was quantified using aerial photography, remote sensing, and GIS to compare the extent and change over time between the eight vegetation classes in the region.^[9] The most striking change between 1974 and 1987 was the considerable fragmentation of vegetation classes. This patchiness of the landscape is indicative of loss of biodiversity and could be an early warning of desertification in the area.^[9]

A multiagency, multinational, global change initiative to investigate the consequences of natural and human-induced environmental change in semiarid regions was started in 1995 in the San Pedro River Basin. Several multidisciplinary projects have been initiated, and ASTER imagery is being acquired for the region. Among the studies being conducted in the San Pedro River Basin is an alternative futures assessment. This latter study has the following two objectives: to develop an array of plausible alternative patterns of land use and to assess their impacts on biodiversity, vegetation dynamics, fire regimes, hydrology, and aesthetics; and as a pilot study to develop a methodology applicable to other areas.^[31]

CONCLUSION

Desertification impacts on landscapes, biodiversity, and human populations are moderately well documented, and there are numerous suites of indicators in use for assessment and monitoring.^[20] Studies of the actual processes involved are valuable, particularly in areas that are marginal for desertification susceptibility, and are contributing to our understanding and therefore to our ability to meaningfully intervene to reduce or mitigate the effects of desertification on both the environment and human populations.^[18]

In the long term, we do not know what "desertification" really means, nor what the impacts to humans, flora, fauna, and the landscape will be. Desertification is a phenomenon that will not disappear as a result of human intervention but may be reduced in severity or extent by a strategy including increasing the understanding of processes involved, monitoring, and investigating alternative management options. In particular, the societal impacts of desertification may be mitigated by involving local communities in the policy and decision-making process.

Abstract

Mapping desertification has proven to be a challenging task. Difficulties derive from its ambiguous definition and the comprehensive integration of various biophysical and socioeconomic indicators that need to be considered in the evaluation process. In the early 1990s, assessments and mapping were based primarily on expert opinions that introduced uncertainties and obvious shortcomings. Later on, with the development of the remote sensing technology and the advancement of the geographic information systems, global mapping became commonplace. Results showed that temporal and spatial scales are crucial components of the mapping and assessment process, but great difficulties arose comparing maps that were developed using different methodologies. Global maps could depict only general trends in desertification caused by human-induced land use changes or climatic variations but proved to be of limited value at local level. On the other side, local studies have problems of extrapolation. This necessitates the performance of mapping at various scales, but only after a methodological approach has been developed that accounts for all the components of the desertification process, allowing upscaling from global to local level and vice versa. Desertification mapping is under way by the World Atlas of Desertification (WAD) 3rd edition. The WAD places particular importance on case studies that document local realities affected by desertification as well as mitigation actions. Finally, concerned efforts must be made to develop and implement sustainable land use planning and land management techniques that arrest and reverse the negative consequences of desertification.

INTRODUCTION

What is Desertification?

Desertification is a term widely used by the scientific community and many other stakeholders associated to the United Nations Convention to Combat Desertification (UNCCD), but non-experts often confuse it with naturally occurring deserts.^[1] It was first Lavauden^[2] who used the term in Tunisia describing it as low rangeland productivity due to inadequate management. However, many researchers credit the French ecologist A. Aubréville^[3] who in 1949 applied the term desertification not to drylands, but to the tropical forests of Africa that receive much more rainfall than what conforms the official UNCCD definition. Aubréville noted that the influence of human activities, i.e., cultivation, deforestation, and accelerated erosion, contributed to the process of transformation of tropical forests into savannas and finally into desert-like environments.

It took more than two decades after Aubréville's warnings of desertification before the topic reached the political agenda. This was largely influenced by the impact of extended drought and moving deserts in the West African Sahel in the early 1970s^[4] that brought about the United Nations Conference on Desertification in Nairobi in 1977. Two decades later, the UNCCD entered into force reaffirming a previous United Nations Environment Programme's (UNEP)^[5] definition of desertification with very slight modifications: *desertification is land degradation in arid, semi-arid and dry sub-humid areas resulting from various factors, including climatic variations and human activities* (UNCCD, Article 1). The UNCCD uses the aridity index, calculated as the ratio between mean annual precipitation to mean annual potential evapotranspiration, to identify the drylands of concern. These areas are characterized by large water deficits, because potential evapotranspiration is much greater than precipitation. The aridity indices in the range of 0.05–0.65 (excluding polar and subpolar regions) identify the arid, semiarid, and dry subhumid zones, likely to be affected by desertification.

However, criticism has been raised, for instance, about the exclusion of hyperarid areas.^[6] On the other hand, even Iceland^[7] claims to have desertification problems! No matter the definition, the final outcome of this type of degradation has typically been considered to be either a reduction or a loss of both biological and economic productivity and of environmental quality derived by the complexity of interaction of various biophysical and socioeconomic factors.

The UNCCD definition of desertification has been widely debated over the years. This became even more critical after almost every country in the world signed the Convention, even those not located in the drylands. To overcome this situation and accommodate all the parties of the Convention, a new terminology was introduced by the UNCCD, namely desertification, land degradation, and drought (DLDD), reflecting the subjects the Convention wishes to be responsible for. For instance, Article 2 of Annex V of the UNCCD attempts to broaden the definition of desertification referring to specific conditions in Eastern Europe, mostly covering human-induced soil and land degradation, occurring under climatic regimes that fall outside arid, semiarid, and dry subhumid areas. Land resources in this context include soil, local water resources, and vegetation (or crops), and degradation is an ecological and economic reduction in resource potential, e.g., due to water erosion, wind erosion, a long-term reduction in the diversity of natural vegetation, and salinization and/or sodification. Therefore, in the broadest terms, desertification includes the degradation of land, soil, water, vegetation, and other resources.^[8] No matter the definition debate, the main goal of the Convention remains the same, as defined by its Article 2 that emphasizes effective actions as all levels to combat desertification particularly in Africa.^[9]

Desertification terminology was greatly enriched after the comprehensive analyses of dryland degradation made by Reynolds, Stafford Smith, et al.^[10] and Reynolds, Bastin, et al.^[11] and the appearance of dryland development paradigm (DDP) that shed new light on desertification and placed it into a new perspective. The DDP integrated biophysical and human-induced factors in a complex approach based on five principles used to assess the stability or disturbances and malfunctions of the dryland ecosystems. This is particularly relevant for these areas that despite being characterized generally by lower soil fertility and problematic climate (e.g., low rainfall and high evaporation rate) are home to more than one billion people who depend on them for their very survival.^[12]

The terminology used to describe resource base degradation creates often confusion, especially for the decision-makers, since no clear indication is made about the differences between soil degradation, vegetation degradation, land degradation, and desertification. However, this last is seldom considered as the final product of degradation and *includes all* of the abovementioned forms despite being used mainly to characterize dryland degradation. Problems

are further exacerbated when desertification, mostly a human-induced process, is combined with naturally occurring drought. They both globally cause great losses every year to agricultural production and contribute thus to food insecurity, famine, and poverty and can give rise to social, economic, and political tensions that can cause conflicts, forced migration, and further impoverishment of the local people. UNCCD^[9] places special importance to resource base degradation in terms of physical, chemical, and biological deterioration of the land system and its implications to the well-being of affected desertification areas.

Long before, in 1979, United Nations Food and Agriculture Organization (FAO)^[13] defined degradation as a process that lowers the current and/or future *capability of soils to produce* (quantitatively and/or qualitatively). Historically, this reflects the main school of thought at that time when *soil degradation* was seen purely as a process identified from the biophysical indicators; it was the domain of soil scientists, and few recognized that *land degradation comprises* many components of the land system, of which soil is only a part.

A further development in the terminology of resource base degradation came after the publication of the Millennium Ecosystem Assessment (MEA)^[14] that defined land degradation as *the reduction in the capacity of the land to perform ecosystem goods, functions and services that support the society and development*. MEA deserves credit for the fundamental change in the philosophy of natural resources management that was based since then on ecosystem's functions and services and not on a single component of it, such as the soil.

The Land Degradation Assessment in Drylands (LADA) project funded by the Global Environment Facility, implemented by UNEP, and executed by the United Nations FAO made an important contribution to the study of land degradation in the drylands. LADA operated from 2006 until 2010, and its main objective was to *develop a set of tools and methods to assess and quantify the nature, extent, severity, and impacts of land degradation on dryland ecosystems at a range of spatial and temporal scales*. To achieve this, the project developed its own definition of land degradation that was inspired by the MEA but was slightly changed to reflect the temporal aspect of the process and draw attention to the fact that the value of goods and services are dependent on the stakeholders concerned, and it is therefore a subjective concept.^[15] Full definition of land degradation according to LADA^[16] is as follows: *The reduction in the capacity of the land to produce ecosystem goods and services and assure its functions over a period of time for its beneficiaries*. Further on, LADA performed also a Global Assessment of Land Degradation (GLADA)^[17] and also developed an online Global Land Degradation Information System (GLADIS; http://www.fao.org/nr/lada/index.php?option=com_content&view=article&id=161&Itemid=113&lang=en) that is under improvement.^[16] GLADIS based its assessment on the status and trends of

biomass, soil health, water quality, biodiversity, economic benefit, and social/cultural benefits showing graphically the results in the so-called radar diagrams.

Following the above considerations, desertification includes all forms of resource base degradation deriving from human-induced activities and climatic adversaries and is expressed by the inefficiency of the dryland ecosystems to maintain economic and ecological functions and to provide goods and services.

METHODS AND APPROACHES

Is It Possible to Map Desertification?

Initial mapping efforts

The first assessment of the state of human-induced Global Assessment of Soil Degradation (GLASOD) was published in 1991.^[18] It surprised both the scientific community and many top environmental decision-makers around the world by estimating that 17% of the 11.5 billion hectares of vegetated land on earth was degraded, largely by erosion, and that 1 in 6 hectares of this land could no longer be cultivated.^[19] GLASOD has been debated over the years for its shortcoming, being based on expert opinion and on a mostly qualitative assessment. It produced disputable results and offered poor relationships between soil degradation assessment and policy development and implementation.^[20] However, GLASOD deserves credit because it contributed greatly to raising the profile of soil degradation at the highest levels of decision-making and remains the only reference for soil degradation at a global scale. The GLASOD methodology was applied also regionally in Asia,^[21] Russia,^[22] and Central and Eastern Europe.^[23] In 2003, Lal^[24] modified GLASOD data and based on information from Oldeman^[25] and FAO^[26] estimated the extent of various types of soil degradation globally as well as their distribution on continental level (Table 1).

Attempts to map desertification have been made by various authors.^[27–32] For instance, Eswaran et al.^[33]

developed Fig. 1 estimating the vulnerability to desertification based on a reclassification of global climate and soil maps at a 2-minute grid cell resolution. The same authors also correlated soil data with population density and identified that the Indian subcontinent was at a high risk of being affected by desertification^[34] due to increased human pressure and unfavorable biophysical indicators that could worsen due to climate change.

The advent of remote sensing (RS) and geographical information systems (GIS)

After the GLASOD experience, all other global assessments of desertification have been mainly based on RS technology and GIS applications. GLADA integrated a range of indicators obtained from RS data with existing global data sets and models to identify degrading areas or regions where degradation may have been reversed. Otherwise, this methodology is known as “hot spot” and “bright spot”. The main indicators used in the assessments were net primary productivity (NPP), rainfall use efficiency (RUE), aridity index, rainfall variability, and erosion risk. Furthermore, these indicators were interpreted on the basis of the global land use systems (Fig. 2) and another series of specific indicators typical for a given area such as land cover, urban and protected areas, livestock pressure, irrigation, crops, temperature and thermal regime, rainfall regime, dominant soils and terrain slope, population density, and poverty level.

The remotely sensed normalized difference vegetation index (NDVI) is used as a proxy, and its deviation from the norm serves as an indicator of land degradation and improvement if other factors that may be responsible (climate, soil, terrain, and land use) are accounted for. Rainfall effects may be accounted for by RUE (i.e., NDVI per unit of rainfall) and residual trends of NDVI such as temperature effects by energy use efficiency (derived from annual accumulated temperature). Land degradation is indicated by a declining trend of climate-adjusted NPP and land improvement by an increasing trend. Translation of NDVI to NPP could enable the economic appraisal of land degradation,^[14] and one of

Table 1 Estimates of global extent of soil degradation by different processes.

Region	Total land area (M ha)	Total degraded area (M ha)	Total degraded area (%)	Water erosion (M ha)	Wind erosion (M ha)	Physical degradation (M ha)	Chemical degradation (M ha)
Africa	2,964	494	17	227	186	19	62
Asia	3,085	749	24	441	222	12	74
South America	1,753	243	14	123	42	8	70
Central America	108	63	58	46	5	5	7
North America	2,029	96	5	60	35	1	—
Europe	2,260	218	10	114	42	36	26
Oceania	849	102	12	83	16	2	1
World	13,048	1,965	15	1,094	548	83	240

Fig. 1 Desertification vulnerability based on soil and soil climate data.

such results is shown in Fig. 3. Based on this methodological approach and data provided for the period 1981–2006 deriving from the Global Inventory Modeling and Mapping Studies NDVI database, Bai et al.^[35] reported that 23.54% of the earth is degraded and 1.5 billion people were affected over this period. As the focus in studies such as these and, e.g., GLASOD is different, it is very hard to spatially compare these to deduct what happened to land degradation at global scale within a given period.

Fig. 4 is a most challenging one produced by LADA. It describes the overall status in provision of biophysical ecosystem services and the processes of declining these services by considering the combined value of each biophysical axis (biomass, soil, water, and biodiversity). Data show that 32% of land globally is in areas with high provision of biophysical goods and services status, but with medium to strong degradation processes, while a large part of the global population (27%) lives in areas with a low status and a medium to strong degradation trend.^[36]

The new world atlas of desertification (WAD)

A new initiative to develop, publish, and establish an online digital new WAD^[37] is coordinated by the European Commission (EC) and UNEP. The WAD endorses a new approach that relies on up-to-date information on the combined biophysical and socioeconomic

situation in order to provide a convergence of evidence of potential on-going land degradation processes. Cause–effect analysis of possible land degradation sources also identifies trade-offs and hence offers routes for solutions, such as sustainable land management (SLM) options. WAD intends to be a global updatable reference on where land degradation processes are ongoing and what could be done to reverse these.

WAD is based on the scientific findings that suggest that the manifold reported causes of land degradation can be clustered into well-defined groups or main desertification issues^[38,39] and that these interplay differently at various scales. Using the most up-to-date, and, at global scale, available information on these issues, e.g., on drought, human population changes, and inappropriate land use, it analyses the cause–effect relations with observed land system productivity dynamics as derived from satellite time series and regarding these as coupled processes. Consequently, areas where a single or multitude of land stress processes, such as an apparent reduced land system productivity, drought events, and agriculture intensification or expansion, are simultaneously ongoing are identified as areas probably prone to land degradation. In this way, trade-offs and solution pathways for land use and land use strategies can be better identified.

Addressing one of the major problems in mapping land degradation at various scales, this WAD concept is scale independent. WAD, starting at global level, illustrates how

Fig. 2 Land use systems of the world.

an assessment can be taken down to the local conditions by adding more detailed contextual information while keeping thematic compatibility at all scales. Spatially inventorying such knowledge offers a basis for designing and economically evaluating options to mitigate desertification, in particular through implementation of SLM practices. WAD therefore wants to promote a change from a negative focus on land degradation, e.g., mapping merely problems, to a more useful positive consideration in that areas are marked to a degree that improvements in land management are needed jointly with identification of the causes on which mitigation strategies need to concentrate.

The Joint Research Centre of the EC has developed the land system productivity dynamics data layer and a tool to compile this from RS time series. Figs. 5 and 6 represent an analysis of 15 years of SPOT VGT-based phenology and productive variables, for the period of 1999–2013 at 1-km resolution. It combines long-term undercurrents with performance of productive seasonal biomass developments of the land system. This is not a land degradation map in itself but an important layer for its evaluation.

CONSTRAINTS AND CHALLENGES

If a comparison was to be made between Figs. 1 and 4, very few areas are in common and this, caused by differences in methods and time periods considered, is the crucial handicap in global desertification mapping that often creates confusion for the end users, mostly decision-makers. Fig. 1, for instance, puts almost the whole of China into humid and not vulnerable areas, while the LADA map provides better details on land degradation classes. Same holds true for much of the Western Europe and eastern parts of the United States and Canada.

Other problems related to desertification assessment and mapping are linked to spatial and temporal scales. Such global maps provide only approximate assessments on the distribution of degradation but are insufficiently detailed to be useful at local level. Conversely, the temporal aspect is often a contradictory constraint because if a comparison has to be made between the present status of degradation with an earlier stage, the comparison period has somehow to be established arbitrarily. GLASOD, e.g., used a period of

Global loss of annual net primary productivity between 1981 and 2006

Fig. 3 Global loss of net primary productivity between 1981 and 2006.

Fig. 4 Classes of land degradation.

Fig. 5 Consistent decline in ecosystem productivity.

25 years, but it is often difficult to obtain evidence that conditions were better (or worse) in the past than at present and that the presumed degradation was due to present land use changes.^[15]

Mapping desertification is complicated also by the diversity of methodologies used, the selection of indicators included in the assessments, and the intrinsic complexity of the process itself.^[40] A major constraint though is the perceptive aspect of deciding what land degradation really is. This can only be defined in view of the needed or planned optimal land use combination. For example, a land use change (i.e., infrastructure development, housing, and increased economic activity) might provide better income sources for the local population in the short term, but in the long term, ecosystem's stability could be disturbed and perhaps will never return to its original status. Is this degradation and how to map it? LADA indicated indeed that there are trade-offs between socioeconomic gains and environmental losses and vice versa, and this cannot be captured simply in a single index. Related to this

is that these gains and losses are subjective and depend on the interests of different stakeholders which are often completely different. This is true at all levels, be it local or global. The UNCCD is struggling for years to establish a minimum set of indicators to be used in land degradation and desertification assessments even though yet final agreement is far away.^[41]

However, a global assessment can be undertaken, bringing together the best of the available databases supplemented with proxies, and probably the best option could be to develop a map of pressures of land degradation based on conditions of ecosystems and land use systems.^[42]

Mitigating Desertification and Its Consequences

Until 2013, the UNCCD has held 11 conference of parties (COP) as the highest governing body. At COP8 held in Madrid, Spain, in 2008, the UNCCD adopted the 10-year strategy (2008–2018) that aims *to forge a global partnership to reverse and prevent desertification/land degradation and to mitigate the effects of drought in affected areas in order to support poverty reduction and environmental sustainability*. These goals are under scrutiny of the COP and of the civil society organizations that strongly endorse the bottom-up approach.

Despite criticism on the achievements of the UNCCD, data show that there are many positive results worldwide, demonstrating that when local stakeholders are both managers of natural resources and implementers of the right policies, it is possible to make a change.^[43–46] Surely these results are not attributed solely to UNCCD activities; however, implementing SLM practices could make a difference. The most common SLM techniques include soil and water management (i.e., terracing, contour planting, living barriers, low or no tillage, mulches, cover crops including biological nitrogen-fixing legumes, grazing corridors,

Fig. 6 Global distribution of productivity dynamics.

and water harvesting) and soil fertility management (i.e., manure, compost, biochar, biomass transfer, agroforestry including nitrogen-fixing trees like *Faidherbia albida*, and overall integrated good soil management).

CONCLUSION

The outcomes of assessments of desertification are often debated as they use different methods, measure different variables, and operate at different scales (both temporal and spatial), with some of them focusing on particular bounded systems such as the drylands. This means that the results from different assessments cannot be usefully compared. Despite these issues, in the context of other sustainable development, challenges such as population growth, food security, climate change, and biodiversity loss, nevertheless desertification assessments demonstrate that this is a key issue and that it is likely to worsen unless timely action is taken and appropriate mitigation practices are implemented.

Land degradation is also a natural process. Without soil erosion, neither the fertile Nile floodplain in Egypt, the floodplains of many other valleys around the world, nor most of the Netherlands would exist. The most visible human land degradation impact is probably soil sealing, a “modern” form of desertification present in Europe, in North America, and in the fast-growing economies of China, India, Brazil, South Africa, and Russia and threatening fertile valleys around the world.

Therefore, efforts to map desertification should be accompanied by more emphasis on mapping also sustainable land use practices and by identifying areas that must be protected from unsustainable human activities as the WAD is proposing. The concept of *endangered soil species* should be fostered, especially for the highly productive Mollisols of U.S. soil taxonomy^[47] or the Phaeozems, Kastanozems and Chernozems of the World Reference Base (WRB) for soil resources.^[48] These soils cover only 3% of the global land surface but produce 40% of the global food and 90% of the world's cereals. The United Nations proclaimed 2015 as the International Year of Soils. This is an excellent opportunity to raise awareness on land protection, how to assess it, and to engage in concrete actions to combat desertification and conserve our natural land resources for the future generations.

ACKNOWLEDGMENTS

Authors are grateful to Dr. Freddy Naghtergaele (retired from United Nations Food and Agriculture Organization) for his careful review, comments, and suggestions and to Dr. Robert Jones, retired principal research scientist at Cranfield University, School of Applied Sciences, United Kingdom, for fine-tune editing and adding important information to this entry.

Abstract

Approaches and strategies to prevent and reverse desertification can be broadly grouped as prevention, mitigation, and restoration. Desertification is framed within multiscale, coupled human–environmental dynamics, and thus must be the approaches for prevention and reversal. The development of integrated analytical methods for evaluating and monitoring interventions is crucial. Approaches focus on indicators that relate to ecosystem integrity and services and to human well-being. Lessons learned in the field from implemented projects are discussed.

INTRODUCTION

This entry provides a brief overview of the most significant approaches to prevent and reverse land degradation in drylands, focusing on conceptual frameworks and on methods to monitor and evaluate their impacts. The implementation of mitigation and restoration programs is specifically addressed, with particular reference to the constraints and risk factors.

DESERTIFICATION PREVENTION AND REVERSAL

Desertification is defined here as land degradation in drylands. It results from a long-term unbalance between demand for and supply of ecosystem services, leading to a persistent reduction of the biological and economic productivity and ecological complexity.

The diverse actions that aim at preventing or reversing desertification can be grouped under three major classes: prevention, mitigation, and restoration. Their boundaries are vague and they rather form a continuum of potential actions to be adapted to the particular sites and dynamics through adaptive management approaches (Fig. 1).

Prevention and mitigation actions can be considered as avoidance approaches, either through proactive management efforts where ecological functions are relatively intact or through changes in land use and management, leading to desertification. However, vast areas of drylands are already severely degraded, with reduced plant cover and species

diversity, depleted or eroded soils, and very low potential for spontaneous recovery of ecosystem functions, even when degradation forces are not acting any more. Restoration of these areas is the only option possible to recover ecosystem services that have been lost.

Examples of prevention and mitigation actions include measures to improve water management and agricultural practices. For example, long-term crop rotations with cereals/legumes; more efficient use of fertilizers; improvements in water use efficiency; conservation-minded tillage methods; traditional water-harvesting techniques, water storage; measures that protect soils from erosion, salinization, and other forms of soil degradation; improved crop-livestock integration, combining livestock rearing and cropping; and *in situ* conservation of genetic resources. To create viable livelihood alternatives can also help reduce pressures on drylands. For desertified lands, rehabilitation and restoration approaches often involve the increase and improvement of vegetative cover through, e.g., the establishment of seed banks, reintroduction of selected species, control of invasive species, and reforestation programs. In general, to develop the appropriate engagement between scientific and local environmental knowledge is critically important.

Desertification is driven by a combination of proximate causes and underlying forces, including their interactions and feedbacks, which vary from region to region and change over time.^[1] It is framed within multiscale, coupled human–environmental dynamics,^[2] and thus must be the approaches for desertification prevention and reversal. The relationships between land degradation and its causal

Fig. 1 Continuum of actions to combat desertification and land degradation.

agents are nonlinear and complex. Degradative and aggradative trajectories commonly exhibit hysteresis dynamics, thresholds, and rapid shifts. These relationships are critical in the design of strategies to combat desertification.

Finally, there is growing evidence that land degradation in desertification-prone areas is likely to increase with climate change.^[3] Desertification is linked to biodiversity loss and global climate change through the regulation of water and carbon fluxes, and this perspective requires the development of multifunctional mitigation strategies.

INTEGRATED EVALUATION OF PREVENTION AND RESTORATION ACTIONS

The development of biophysical and socioeconomic integrated analytical methods for evaluating progress and success, along with a framework for knowledge sharing and transfer, is crucial to combating desertification.^[2,4] Furthermore, monitoring and evaluation are needed to demonstrate the benefits of sustainable drylands management, to establish cost-effective thresholds for the various management alternatives, and to identify priority areas where actions could be most effective.

There have been a number of initiatives to develop common and comprehensive methodologies for assessing and evaluating the effectiveness of management and restoration programs.^[5,6] These approaches focus on indicators that relate to ecosystem integrity and services and to human well-being (socioeconomic and cultural variables). Because of the large spatial and temporal variability of dryland systems, it is critical to focus on “slow variables”;^[7] hence the assessment is not confused by short-term variations in land and socioeconomic conditions.

Evaluation frameworks must take account of the cross-scale and social–ecological interactions affecting the response of degraded lands to mitigation/restoration actions.^[8] A multiscale approach is always advisable. Farm- and project-scale assessments focus on local resources and productivity, and private economic valuation perspective (marked prized goods and services), while

landscape- and program-level indicators address environmental benefits and public/social welfare considerations.

IMPLEMENTATION OF MITIGATION AND RESTORATION PROGRAMS

Despite the availability of technological, institutional, and even financial resources, efforts to combat desertification often fail because of a poor implementation. The following cases summarize major constraint or risk factor that can hinder the successful implementation of well-designed projects and highlight the necessary improvements and lessons learned

- Inability to cope with natural crises: especially in projects aimed at increasing plant cover, a poor or delayed wet season or recurrent droughts may cause the loss of the year investment or even of the whole project. Emergency/contingency funds, quick diagnostic and intervention mechanisms, and flexibility in project duration would be needed.
- Lack of longtime planning: very often the longtime dynamics (and its ecological implications) of the newly established systems are not fully considered. This is of particular concern in the case of introducing alien species.
- Passive community participation: community participation should be strongly based on responsible awareness and sharing of project objectives. Sometimes they in fact implement sectoral administration goals, which require farmer action but do not represent the key problem for people.
- Uncertain community commitment: the representativity of the community can be a problem. Who is committing on behalf of whom? The commitment should include economic participation, be linked to final results and based on ownership and responsibility after the project ends, more than related to single tasks.
- Institutional commitment: complex projects, in which the implementation is based on the support of local

administration staff, need a formal and clear institutional commitment. This may take time and very rarely can be established before project approval: projects should have an inception phase to set agreements.

- Schematic approach: sometimes big programs are extensively implemented, often through private sub-contracting, by adopting schematic approaches, which are not able to adapt to specific local land features and people needs, or are too easily funded in areas where they are not necessary or even have negative side impacts. Implementation protocols with multiple technical solutions are needed.
- Lack of assessment: projects are often not adequately monitored and assessed, so lessons are learned too late. Suitable indicators and methods are needed.
- Socioeconomic and demographic dynamics: some projects have experienced lack of man power due to young people migration. Furthermore, the return of people on the land previously “closed for restoration” may cause unsustainable pressure. Mitigation of poverty and migration in the short term should precede/accompany the benefits of medium-term land conservation.
- Market drivers: the dynamics of international and local market prices may completely revert in a few years the achievements produced by years of conservation programmes.
- Contrasting policies: farming incentives may generate negative impacts contrasting mitigation programmes, if not accompanied by adequate guidelines.
- Short time projects: very often project duration imposed by donors (3–5 years) is too short to allow for effective “inception or learning phases,” to deal with the necessity to adapt to changing conditions and needs, to cope with unforeseen events and delays, and most of all to monitor and assess project impacts and sustainability.

CONCLUSION

The brief analysis performed underlined a range of key methodological issues and knowledge gaps, such as threshold conditions and the impact of mitigation and restoration actions on carbon and water cycles and on biodiversity. These should become the basis to develop multifunctional mitigation strategies and formulate inter-linked policies to address desertification, climate change, and biodiversity.

Lessons learned in the field highlighted several issues threatening the success of prevention/reversal actions. The adoption of extensively schematic approaches with poor ex-ante evaluation and scarce integration of sectoral

strategies are among the more critical aspects. Community participation and commitment must receive great attention.^[9] In particular, the development of participatory approaches in the assessment of interventions, including capacity building and information circulation, is critical to improve the adoption of cost-effective, environmentally sound mitigation and restoration measures. Desertification: Productivity

Kris M. Havstad

Jornada Experimental Range, U.S. Department of Agriculture (USDA), Las Cruces, New Mexico, U.S.A.

Abstract

Despite the increase in desertified lands during the 20th century, the world's populations of cattle, sheep, and goats have collectively increased from 1% to 1.5% annually since World War II. Effects of desertification on primary or secondary productivity of rangelands will be related to resulting species alterations and/or changes on water and nutrient economics.

INTRODUCTION

The United Nations convention to combat desertification (UN-CCD) defined desertification as the degradation of land in arid, semiarid, and dry subhumid areas resulting from various factors, including climatic variations and human activities.^[1] These susceptible drylands cover approximately 40% of the world's land surface.^[2] Desertification is not a new problem, but one that traces back to 2200 B.C. and the degradation of Mesopotamia.^[3] However, the estimated extent of degradation of the world's dry lands at the end of the second millennium A.D. is substantial (Table 1).^[2] Although estimates of the magnitude of degradation vary widely, it is documented that soils of at least 12% of the world's 5169 m ha of drylands are at least moderately desertified.^[2] It should also be noted that these estimates often do not consider lands outside the world's subtropics.^[4] The UN-CCD^[1] estimates that over 250 million people are affected by desertification with about one-sixth of the world's population at risk.^[1] For some continents, the numbers of people at risk are much greater. In Africa, Asia, and South America, between 30% and 40% of the populations live within these susceptible drylands.^[2] Generally, the effects of this land degradation are reductions in desirable plant production, alterations in biomass, lowered carrying capacities for livestock, increased soil erosion, and an overall increase in environmental deterioration.^[5] It is usually assumed that desertification has direct and measurable effects on either primary or secondary production from these lands. In very severely desertified situations, such as Southern Kazakhstan, productivity has been dramatically reduced.^[6] For other regions of the world where desertification is certainly serious but not severe, the relationships between degradation and productivity are less obvious and direct. These relationships need to be understood so that measures other than simply productivity

reductions are employed to accurately assess rates, extent, and threats of degradation to these land resources.

PRIMARY PRODUCTIVITY

Primary productivity is defined as the fixation of carbon dioxide into organic molecules by photosynthetic organisms. Typically, agriculturally and ecologically based estimates of primary productivity focus on some aspect of annual above ground net primary productivity (ANPP). For crop lands, this may be annual grain yields, and reductions in yield of 25% or more have been reported for dry land and irrigated crops.^[7] Often, these losses in productivity are coupled to increased soil erosion because of degradation. For rangelands, primary production is often expressed as biomass production on a dry matter basis per some unit area. Plant processes affected by degradation include reproduction, germination, establishment, survival, and competition, and adverse effects on these processes can result in reductions in ANPP. As a result, there are a number of documented reports from different continents where these shifts have resulted in large declines in primary productivity.^[8] The initial effects of chronic disturbances on these processes may result in structural changes in vegetation such as a shift from herbaceous to woody dominated plant communities, and these structural changes do not always result in reductions in primary productivity.^[9,10] For example, in the northern Chihuahuan Desert of North America, ANPP does not differ among major vegetation types, including shrub land types that are regarded as degraded from the historic desert grasslands.^[11] These types do differ in other vegetation attributes including species richness and in their seasonality of production. Irrespective, seasonal measures of primary production in heterogeneous environments are extremely variable both temporally and spatially.^[12] Thus, it is difficult to consistently and directly equate reductions

Table 1 Soil degradation (from light to severe) by region of the drylands of the world (arid, semiarid, and dry subhumid regions).

Continent	m ha	%
Africa	319.4	25
Asia	370.3	22
Australia and New Zealand	87.5	13
Europe	99.4	33
North and Central America	79.5	11
South America	79.1	15

Source: From Middleton & Thomas.^[2]

in primary productivity in all rangeland environments with desertification.

SECONDARY PRODUCTIVITY

Secondary productivity is the transfer of energy from primary producers to consumers and is often expressed as animal production. For the world's rangelands, secondary production is often measured in terms of livestock productivity. There are specific instances where desertification has resulted in a documented decline in livestock stocking rates, such as in the Western Cape of South Africa.^[13] However, in many instances, losses of stocking rates have not been directly linked to desertification, and loss of secondary productivity can be an ineffective indicator of degradation.^[7] For example, looking more broadly at South Africa during the last half of the 20th century, livestock numbers have been fairly stable.^[14] A more effective indicator of desertification may not be the total number of livestock, but the shift in livestock species used as vegetation types typically changes from herbaceous to more woody species with degradation.^[15]

CONCLUSION

Despite the increase in desertified lands during the 20th century, the world's populations of cattle, sheep, and goats have collectively increased from 1% to 1.5% annually since World War II.^[16,17] This is an increase of 1.8 billion head of livestock over the 1940s, and the increase has been spatially heterogeneous. For example, cattle, sheep, and goat numbers in Africa and Asia have increased over 80% since World War II and comprise 65% of the world's total population. Sixty-five percent of the global increase in sheep numbers has occurred in Asia. These continents have reported extensive desertification during the 20th century. Declines in numbers of livestock may be misleading as an indicator of desertification at regional, national, and continental scales.

Hoffman^[18] has described five phases of vegetation change during the degradation of the Karoo in South

Africa. These were: 1) primary degradation with a loss of cover, primarily palatable perennial grasses and shrubs; 2) denudation with further loss of palatable plants, an increase in unpalatable species, and accelerated rates of erosion; 3) revegetation with an increase in unpalatable species, particularly woody plants; 4) secondary degradation with a relatively stable community of undesirable plants; and 5) desertification with loss of most plant species other than a few hardy shrubs, a soil surface widely exposed to accelerated erosion, and invasion by exotics. Similar vegetation dynamics have been described for other dry land environments in response to overgrazing and prolonged drought. Throughout these phases primary and secondary productivity may or may not be reduced. In general, effects of desertification on primary or secondary productivity of rangelands will be related to resulting species alterations and/or changes on water and nutrient economics.^[19]

Desertification: Restoration

Alon Tal

Mitrani Department of Desert Ecology, Jacob Blaustein Institute for Desert Research, Ben Gurion University, Beer-Sheva, Israel

Abstract

The impacts of land degradation are limited not solely to soil loss through erosion but also to their subsequent role in reducing the biological and economic productivity of drylands. Reversing desertification, therefore, requires the restoration of the ecosystem's state, function, and services that have suffered or even disappeared in degraded drylands. Because of the soil's reduced water holding capacity and poor productivity, restoration tends to be even slower in desertified areas than in non-dryland regions experiencing land degradation. Two stages of activities are necessary for restoring ecosystems in desertified areas: removing disturbances to the lands and putting forth proactive efforts to restore the flora and fauna to degraded regions. In semiarid and arid regions, special importance is also given to managing watershed regimes and, when possible, reinstating natural flood patterns.

INTRODUCTION: RESTORATION ECOLOGY AND THE DRYLANDS

Activities designed to restore degraded drylands should draw from the fundamental principles of the relatively new field of restoration ecology. Ecological restoration is typically defined as “an intentional activity that initiates or accelerates the recovery of an ecosystem with respect to its health, integrity, and sustainability.”^[1] The original ecosystems that suffer desertification can be woodland, rangeland, or cropland, each with its specific functions and associated strategies/nuances for successful restoration. Yet, typically two types or stages of activities are necessary for restoring ecosystems in desertified areas: removing disturbances to the lands and putting forth proactive efforts to restore flora and fauna to degraded regions.

The climatic and the biotic context that distinguishes desertification from general soil degradation also informs about restoration strategies. The United Nations' legal definition characterizes desertification as “land degradation in arid, semiarid and dry subhumid areas resulting from various factors, including climatic variations and human activities.”^[2] The impacts of land degradation are limited not solely to soil loss through erosion but also to their subsequent role in reducing the biological or economic productivity of drylands. Reversing desertification, therefore, requires the restoration of ecosystem state, function, and services that have suffered or even disappeared in degraded drylands.^[3] As natural communities are primarily composed of plants, restoration ecology for the drylands tends to rely on botanical science.^[4] In semiarid and arid regions, special importance is also given to managing watershed

regimes and, when possible, reinstating natural flood patterns which affect taxa richness in general and micro-invertebrate communities in particular.

Restoration policies must clearly articulate which ecosystem services are to be restored. For instance, farmers may not be inclined to convert eroded farmlands back to original grasslands but may still seek to increase the sustainability of their agricultural practices. Indeed, while restoration efforts aspire to recover or reconstruct the original functioning communities, this typically does not imply a return to the pristine conditions which existed prior to human disturbance. Such an ambitious objective may not be realistic or even desirable.

Degraded drylands may be in such an advanced or enduring state that while it may be possible to assess the original indigenous communities and roughly estimate an appropriate distribution of species, given the nonlinear function associated with biodiversity loss, the damage may be impossible to reverse. In the cases where abiotic conditions have changed dramatically owing to land contamination (e.g., salination), or diversion of natural drainage, restoration efforts will only be able to approximate original conditions. These more modest efforts have come to be called “rehabilitation.” Similarly, others endorse creative efforts to restore ecosystems, even in areas of relatively intense human settlements, calling for a “reconciliation ecology.”^[5] This entry will include both of these approaches under the general title of ecological “restoration.” Yet, restoration, rehabilitation, and reconciliation activities should all seek to return key components and interactions of the original ecosystem and assist in the damaged ecosystem's recovery.

Returning lands to previous levels of biological productivity and diversity is a protracted process. Ecological restoration tends to be even slower in desertified areas than in non-dryland regions experiencing land degradation. This happens because of the soil's reduced water holding capacity and poor productivity or in the cases of soil salination, where water availability is critical for leaching of salts. Accordingly, to attain reasonable progress in highly degraded areas, more aggressive interventions to expedite the increase in ecosystem services and soil productivity are generally necessary. The temporal concerns that drive restoration strategies need to be informed by spatial consideration. A basic principle of restoration ecology recognizes the close association between the scale of an ecosystem's disturbance and the amount of time required for its restoration. When desertification takes place in a relatively small area, restoration can be attained far more quickly than in larger areas.^[6]

REMOVAL OF DISTURBANCES

If the causes of the desertification process are not addressed, then proactive restoration efforts that focus on the symptoms will be unsuccessful. The reversal of desertification, therefore, begins with the removal of the direct drivers that were the proximate cause of the desertification and ecosystem functioning loss in the first place. In agricultural areas, this can mean the cessation of unsustainable cultivation practices—from plowing and planting on excessively steep gradients to excessive pesticide application—alongside the adoption of traditional soil conservation practices, such as terracing or no-till plowing that can prevent erosion processes. If soil degradation is a result of deforestation and loss of land cover, then rules must be enacted to enjoin wood clearing. In drylands, unsustainable water management decisions can be among the primary drivers of desertification, and restoration strategies must ensure that they include prescriptive and enforcement efforts throughout the watershed.

Ecosystem restoration often also requires the consideration of relevant zoological factors, e.g., removal of problematic exotic species/herbivores. For instance, in a semiarid region of Chile, removal of herbivores (in particular European rabbits) increased sapling survival by as much as 60% in a controlled restoration experiment.^[7] In degraded areas which are tourist destinations, restoration programs may need to enact limitations on off-road vehicle or human access. Moreover, a sustainable restoration strategy must also address the indirect human forces that influence the biophysical processes.^[8] This can involve the introduction of social policies ranging from the reduction of population pressures or enhancing the status of women (who are frequently excluded from soil conservation decisions, notwithstanding their key role as farmers) to the modifying market incentives that encourage poor land

stewardship. Given the prevalence of pastoral activities in the drylands, controlling overgrazing is among the most common measures that must be taken to create the potential for the restoration of desertified ecosystems.

Sustainable Grazing

Historically, the seasonal migrations of pastoralists from China to the Sahel indigenous and their nomadic herds did not necessarily exceed ecosystem carrying capacity and in many cases may actually have contributed to long-term sustainability and biodiversity.^[9] Yet the steady shrinking of available rangelands, population increase among pastoral communities, and their associated activities along with the steady improvement of veterinary practices in the modern period have led to increasing pressure on rangelands worldwide. In the drylands, where soils are generally nutrient poor and water constrains rangeland resilience, overgrazing has led to excessive soil compaction, loss of soil cover, soil erosion, and in many cases the conversion of grasslands to shrublands—leading to increased runoff, soil heterogeneity, and state change. In areas where grazing has led to the decimation of land cover, stocking limits that prescribe maximum animal densities are relatively easy regulations to enforce and constitute a normative prerequisite to ecosystem restoration efforts.^[10]

When managed appropriately, grazing produces net ecological benefits. Removal of biomass reduces fodder available for bushfires. Livestock can facilitate the spreading of seeds, with manure providing limited available fertilization on nutrient poor lands. When optimized, grazing can be a key element in restoring ecosystems, assisting the growth of grasses, breaking detrimental soil crusts, and enhancing biodiversity, by controlling plants that would otherwise become dominant. For example, in Israel, afforestation has proven to be an effective mechanism for reducing dryland soil erosion. In these woodlands, grazing by indigenous bedouin has proven to be so important in local strategies to prevent forest fires that in some areas grazing fees on public lands have been reversed, and foresters are paying herders to bring their sheep in a controlled grazing regime into the forests to clear out grasses and shrubs. (Ironically, in areas with greater rainfall and tree densities, initiating fires has become a key land management tool.)

Accordingly, ecological restoration efforts should characterize the level of land resilience which varies according to soil type, rainfall patterns, etc. Subsequently, they should permit grazing that does not exceed the carrying capacity. The impacts of reduced grazing are clearly manifested along the Israeli–Egyptian border. When Egypt reclaimed the Sinai Peninsula, within a few years, satellite images identified a geopolitical border. On the Israeli side, a biogenic crust remained intact, reflecting the continuation of grazing regulations, as opposed to the dramatic loss of land cover in Egypt where grazing restrictions were relaxed.^[11]

Seemingly degraded lands will often return to their pre-grazing state following the cessation or reduction of grazing, with natural seed banks containing sufficiently viable seeds to reestablish high-diverse, indigenous plant cover. In a retrospective study of five sites where degraded sites were fenced off from grazing animals in Northern China, 15 years after the intervention, the vegetative species restoration in the protected sites was deemed to be more successful and effective than comparable areas where aerial seeding alone was conducted.^[12] The ultimate test of success of such interventions, however, can only be measured by the ability of restored sites to once again withstand a controlled grazing presence.

Controlled grazing need not imply fencing or the truncation of traditional grazing routes. Rangeland carrying capacity can be maintained by migration and rotation. Indeed, “reaggregation policies” can offer a more sustainable alternative; seasonal movement by pastoral communities across private and communally owned lands is facilitated, as nomadic pastoralists continue to rotate their flocks.^[13] Calculating precise carrying capacity for grazing herds tends to be site specific and requires monitoring to assess the validity of initial estimates.

RESTORING VEGETATION, WILDLIFE, AND DRAINAGE PATTERNS

While research in ecosystem succession suggests that following the removal of disturbances, dryland ecosystems will recover naturally, ongoing soil loss may be sufficient or so far advanced as to justify proactive remedial measures. Desertification is frequently a direct result of soil exposure following the loss of vegetative cover. Hence, restoring trees and grasses cover is generally a key component of ecological restoration. Among the range of practices that have been successfully employed are the replenishment of organic materials and nutrients in the soil, aerial seeding, and artificial restocking of natural seed banks, reforestation, and planting of grasslands, seed inoculation with organisms that support plant growth, and species reintroduction along with soil conservation activities such as gulley controls or road replanning.

Restoration of Vegetation

Vegetation and reforestation programs depend on local climatic and soil conditions as well as the original, indigenous vegetation types. The introduction of plant species that are known to have existed on the degraded land prior to human disturbances is a typical strategy, especially when agriculture or human settlement has erased original flora. An underlying assumption behind such an approach is that as abiotic conditions remain unchanged, the ultimate mix will approximately come to resemble the original plant combinations. The introduction of shrubs and grasses is thought

to be more cost-effective as a means for reducing erosion than are trees in dryland restoration efforts although dryland forestry has proven to be successful in a variety of regions.

In general, restoration strategies that run counter to botanical succession patterns will tend to be less successful than those that emulate them. For instance, the “Great Green Wall,” initiated in 1978 in Northern China, may be the most ambitious land restoration project undertaken in a desertified region. The results have been disappointing, not withstanding considerable government investment. Local researchers suggest that the prevailing 350-mm rainfall and high evaporation levels are unable to support the type of woodlands introduced.^[12] Afforestation efforts in Israel have established relatively dense canopies as well as new habitats and recreational venues in semiarid climates with as little as 250 mm of annual rainfall. While in Mediterranean regions of the country, 2nd generation forests have emerged; returning original stands of oak-pistacia woodlands, the low rate of natural regeneration in semiarid conifer forests raises questions about the long-term sustainability.

Because moisture is generally the greatest controlling factor in dryland ecosystem restoration, attention should be given to the availability of water and homogeneity of runoff. In areas where there has been desertification of productive grasslands, the resulting heterogeneity of runoff can produce a loss of soil and nutrients that can ultimately lead to a change of state, with new invasive shrub communities emerging.^[14] Returning grasslands to such semiarid and dry subhumid lands through proactive seeding will improve rainfall infiltration and begin to reverse runoff and erosion intensity.^[15]

In areas of low precipitation, vegetation in the drylands is often naturally sparse, with vegetative patches surrounded by exposed soils with biogenic crusts. Vegetation is present as steppes that often take on a spotted or banded structural formation. Indeed, Chinese land managers generally see 30% vegetative cover of soils as sufficient to prevent wind erosion.^[16] Accordingly, the rejuvenation of grasslands and woodlands need not aspire to reach full coverage. Studies in New Mexico showed that net primary productivity in shrublands was comparable to the native grasslands, even as the economic utility of grasslands is considered to be greater, given their higher levels of support for grazing.^[14] Drylands probably select for shrub species that are better able to exploit the moisture available in the deeper soil layers after intermittent, intensive rainfall events as well as for crust species that enable shrubs to harvest the deeper waters.

The ecological interactions in the patchy, so-called “resource islands” are generally characterized by facilitation between plant species, a dynamic that can and should be utilized in restoration activities in the drylands. Existing vegetation can be utilized to provide microsites for the introduction of desirable species. Seedling survival and

growth in drylands are generally far higher when planted under the canopy of shrubs or trees than in open areas. For example, in Spain, shrubs were more successfully reestablished near existing tussocks than in open semiarid areas that served as controls;^[15] in Kenya, planting aloe improved the effectiveness of grass reseeding on degraded rangelands.^[17] In a restored Israeli degraded site, artificially created pits served as sinks that reduced leakages of water, soil, and nutrients. The result was a significant increase in total biomass production as well as annual plant species diversity.^[18]

The patchiness of vegetation in drylands makes natural seed limitation a key obstacle in restoration efforts with the result often being incomplete species assemblies. Direct seeding via the air dispersal or less costly conventional methods offer the most common method for overcoming the loss of deep-rooted perennial plants and accelerating the vegetative change. As ecological restoration typically seeks to reinforce indigenous species, the collection of seeds from native species constitutes a considerable logistical and economic challenge. It is important, therefore, to create conditions that ensure the maximum success of seeding efforts. Survival rates for seedlings are usually increased by moderate soil disturbance (e.g., harrowing or raking) prior to the spreading of seeds. Ensuring the availability of nitrogen, phosphorus, and potassium is critical, as the runoff produced by degraded shrublands often leads to a poor key elements land. Microbial symbionts are also an important supplement in seeding efforts.

The Role of Soil Microbes

Loss of vegetative cover is often preceded by damage to basic soil properties such as nutrient concentrations, soil structure, organic matter content, and microbial activities. Microbial symbionts, the microorganisms that inhabit upper layers of the soil, play a key role in governing nutrient cycles in plants, maintaining symbiotic relationships with root systems. While agriculture and forestry have focused on these interactions for sometime, only lately has the potential role of mutualistic soil organisms in reestablishing native plant communities in desertified regions been demonstrated.^[19]

Of particular importance are the mycorrhizal fungi that strengthen the ability of plants to cope with stress and rhizobia, which facilitate the fixing of nitrogen and allow plants to grow even when available nitrogen in soils is low. In essence, their presence extends surface area of roots several hundred times, allowing plants to overcome heat and drought as they more efficaciously absorb water and nutrients. Because these organisms are dependent on the presence of native host plants, especially legumes, frequently a depletion of microbial symbionts will accompany loss of vegetative cover. In addition, arbuscular mycorrhizal fungi have been demonstrated to increase phosphorous uptake.

When ecological restoration involves the planting of legumes, the inoculation of seeds with rhizobia has proven to be effective. This holds true for trees as well. In an Australian study, inoculated native acacia seedlings grew 10–58% faster than uninoculated controls.^[20] Research in Mediterranean ecosystems demonstrated that plants introduced after inoculation with mycorrhizal fungi and rhizobial ecosymbionts showed significant advantages in five-year survival rates and size. Furthermore, measurable improvements found in the soil's physiochemical properties included higher nitrogen concentrations, organic matter, and soil aggregation after inoculation.^[19]

Restoration of Animals to Desertified Ecosystems

Loss of wildlife and changes in fauna formations in desertified systems may be affected by causes of biodiversity loss that are not directly associated with land degradation (hunting, habitat loss, etc.). Concern has also been expressed for the impact of climate change on population dynamics in drylands due to the anticipated increase in interannual variance in arid environments.^[21] Hence, restoration programs should consider general conservation measures that can be applied in conjunction with proactive animal repatriation on desertified lands efforts. When vegetation returns to its natural state, assuming that there have not been local extinctions, wildlife should eventually return to its original diversity and levels. Organisms which have evolved to accommodate the extreme climatic conditions of the drylands may be well equipped for relatively harsh physiological and behavioral adaption imposed by moderate changes in soil. Yet, the reduction in vegetative productivity will ultimately be felt along the food chain, and its rejuvenation holds the key to successful repatriation of native wildlife. For instance, after the restoration of vegetation to a hyperarid, dry salt marsh north of the Gulf of Aqaba (which had been converted to a garbage tip), bird populations returned during their migrations from Africa to Europe.^[22]

The reintroductions of animal species that have disappeared have been successful in such dryland countries as the United States, Spain, Oman, and Israel. These are generally popular with the public although they are typically expensive,^[23] and failure is more common than success. The International Union for Conservation of Nature (IUCN) has formed a "Reintroduction Specialist Group" that has, for some time, drafted animal-specific release protocols, which take into consideration the climatic conditions in drylands. Given the economic role of grazing in drylands, finding the optimal balance between domestic and wild animals in restored areas may not be self-evident and should be clarified when establishing restoration objectives. Frequently, restoration strategies will have to weigh competing priorities (e.g., fencing versus preservation of migration routes). Moreover, restoring top predators populations is often the best practice but will cause

tension between conservationists and domestic herd owners. One should also take into consideration that restoring desertified land can change the local species communities.

REINSTATING DRAINAGE AND FLOODING PATTERNS

As limited water resources are taken for irrigation and other human uses, the natural flooding patterns in drylands are often disturbed, affecting the natural ecosystems. As ground water tables drop and runoff no longer reaches open spaces, vegetative response is often dramatic. In areas where water has been tapped for human endeavors, meaningful ecological restoration cannot take place without reinstating some meaningful portion of runoff and approximating original drainage patterns. Especially in semiarid and arid zones, periodic floods also allow for colonization by micro-invertebrates, insects, and autotrophic communities, which in turn attract avian populations. Of particular importance to ecological restoration efforts in drylands is the shortening of the duration of protracted dry periods by ensuring reasonable frequency of floods that preserve micro-invertebrate and macrophyte populations in their resistant stages. For example, using emergence of micro-invertebrates from resting eggs as an indicator, an Australian study, along the arid floodplains, showed that increased drying significantly reduced taxa richness.^[24]

Water extraction is not the only way that hydrology can affect ecosystems. Often, land use activities in the upper reaches of a watershed are the primary cause of soil loss. For instance, the narrowing of gullies or poorly designed roads can speed water flow and exacerbate the erosive effects of storms. Identifying causes as opposed to mere symptoms implies that restoration activities in the lower sections of such a watershed will be undermined by new, erosive flow patterns unless interventions are made to reduce flow velocity. Increasing the meandering pathway of ephemeral streams or building terraces and dikes has attenuated floods and helped approximate original, basin-wide flows.

CONCLUSION

Severe desertification reflects a change in state, where key thresholds have been crossed.^[16] It is invariably easier to remedy a situation prior to a shift into a new, degraded state, then to restore a decimated ecosystem. Ongoing monitoring of soil and ecosystem conditions to identify gradual degradation is, of course, advisable. Notwithstanding lack of international progress in combating desertification, land degradation trends need not be destiny. International experience demonstrates that the restoration of desertified ecosystems is possible. Restoration efforts require patience and prolonged attention from

government the decision-makers, land managers, rangers, and general public. After removing the proximate and indirect drivers of the land degradation, proactive efforts can be cost-effective. In addition to ensuring the general application of soil conservation, activities in a watershed should include the thoughtful selection of indigenous plant and wildlife and their introduction with appropriate technologies (e.g., reestablishment of microbial symbionts). When such measures are supported by community involvement and appropriate policies, it is possible to reestablish healthy and productive ecosystems in desertified lands.

Abstract

This entry describes an ecologically-based set of data-gathering processes by which desertification can be assessed and combated using a framework that characterizes the biogeochemical status of the system. This can be simply expressed as “assessing the regulation of vital resources in space and time.” The procedure is able to deliver biogeochemical solutions appropriate to the problem, rather than a set of recipes with varying degrees of potential success. The information-gathering procedure can be adapted to a wide range of bioclimatic situations, because it deals with the basic processes controlling the availability of vital resources to biota.

INTRODUCTION

The term “desertification” was coined to graphically represent the state of the Sahelian lands in the 1970s, when major drought accompanied by major increases in the human population served to cause the desert margins to apparently move into formerly more productive land.^[1,2] The image of an encroaching desert is powerful and evocative and resulted in major international efforts to understand and deal with the problem. Since that time, the notion of desertification has been reworked in light of additional information to the extent that the desert is no longer seen as inexorably increasing in size nor restricted to the Sahel.^[3–5] Most rangeland areas in the world have suffered some sort of degradation, and reviews^[6] have shown the process to be not at all restricted to hot deserts or areas of high population density. This is not to deny, however, the major effects on the human populations using these lands, and no doubt, much human hardship has been endured.

biogeochemical systems, with logical sequences of processes and feedback loops.

Vital resources such as water, nutrients, and topsoil are distributed, utilized, and cycled in space and time by processes such as runoff/run-on, erosion/deposition, and decomposition.^[8,10,11] Landscapes are said to be “functional” or non-desertified, if resources are retained within the system and utilization and cycling processes are efficient. “Dysfunctional” or desertified landscapes are characterized by the depletion of the stock of some vital resources and the continued flow of these resources out of the system. This mindset emphasizes the system attributes of processes acting in space, over time, in relation to applied stress and disturbance, rather than just the change in the lists of species or yields of commodities. The role of vegetation as a significant regulator of energy and resources is integral to this approach.^[12] Desertification should be viewed as a continuum ranging from slight to severe, rather than as a simple step function (Fig. 1).

DESERTIFICATION REDEFINED

This entry focuses on the biophysical aspects of desertification. Traditionally, easy-to-measure plant structural attributes, such as species composition and productivity, were the means by which desertification was assessed. These methods served to show the effect of desertification, but did not provide a predictive understanding of how to combat it. However, advances in landscape and restoration ecology^[7–9] have proposed generic approaches to study the basic nature and reversibility of desertification. Principally, this involves treating the affected landscapes as

ASSESSING THE DEGREE OF DESERTIFICATION

If field sites were characterized according to “resource regulation” capacity, not only could the degree of desertification be assessed, but also the critical pathway of resource loss might be identified. Tongway and Hindley^[13,14] have designed and implemented monitoring programs to quickly provide information about biophysical processes and edaphic properties related to plant habitat favorability at both landscape and plot scales. The data gathered need an interpretational framework to facilitate generic application. Graetz and Ludwig^[15] proposed that system response to

Fig. 1 Desertification as a continuum. The four new biophysical parameters (bold) are added to the two existing desertification descriptors (dotted box) to locate any given landscape on the continuum.

desertification be represented by a four-parameter sigmoidal curve. Their field data analysis suggested that this shape was appropriate to relate landscape function to the degree of stress and disturbance, causing the dysfunction. The curve form acknowledges upper and lower asymptotic plateaus at the non-desertified ends and highly desertified ends of the spectrum, respectively, and a transition between those plateaus. This approach permits questions about whether a system was “fragile”—easily made, dysfunctional, with low restoration potential—or “robust”—able to withstand stress and disturbance with only small biogeochemical attenuation (Fig. 2) to be asked. Importantly, this curve type enables critical thresholds to be detected and quantified using field indicators.^[16]

Fig. 2 Examples of response curves for fragile and robust landscapes. The initial response of landscape function to stress and/or disturbance is markedly different. The fragile landscape deteriorates with low applied stress and has a much lower base value (y_0) than the more robust landscape. Four-parameter sigmoid curves of the form $y = (y_0 + a)/(1 + e^{-(x-x_0)/b})$ provide four practical values reflecting the nature of the landscape. Critical thresholds (arrows) for each index of desertification can be determined by curve analysis.

PROCEDURES TO REVERSE DESERTIFICATION

Rehabilitation of desertified landscapes, under the biogeochemical system mindset, requires that processes that accumulate resources be reintroduced, thus providing a rational procedure in restoration of desertified landscapes. The approach explicitly seeks to retain resources by ecological processes.^[9,17,18] Once the analysis of resource regulation system has been completed and the most affected process have been identified, remedial efforts can begin; e.g., Rhodes and Ringrose-Voase^[19] deduced that ponding water on swelling clay soils would eventually result in open, friable soils with high infiltration and water store through swelling and shrinking processes. Tongway and Ludwig^[17] used piles of branches arranged on the contour line to trap water, sediment, and organic matter to effect substantial improvements in a range of soil properties, permitting perennial grasses to self-establish. Both these procedures were effective because each had identified the critical biophysical process to be ameliorated in their respective landscapes. Attempting to revegetate desertified areas by simply reseeding without understanding both the existing and the required edaphic properties needed for the desired vegetation mix frequently results in unexplained failure. In some instances, where the system function is close to the lower asymptote (Fig. 2), simple treatments such as exclusion from grazing will be too slow or ineffective, and active intervention may be needed to improve one or more functional processes.

MONITORING REHABILITATION

It will be important to monitor the progress of processes set in train by the rehabilitation activities. Essentially, the degradation curves such as those in Fig. 2 need to be driven “in reverse.” The procedure proposed by Tongway and Hindley^[20,21] can be used to follow the trajectory of the system. The procedures use simple, easily observed indicators of processes of resource regulation. Biota establishment and development will also need to be monitored and interpreted in terms of the response of the whole system to restoration. It is important that the monitoring process should provide accurate information quickly and at low cost. Remotely sensed data related to landscape function is a cost-effective procedure.^[22] Also, the effect of rare stochastic events such as fire may need to be assessed to see whether the resultant stress and disturbance have set the system back beyond a critical threshold or not.

CONCLUSION

We have described an ecologically based set of data-gathering processes by which desertification can be assessed and combated using a framework that characterizes the biogeochemical status of the system. This can

be simply expressed as “assessing the regulation of vital resources in space and time.” The procedure is able to deliver biogeochemical solutions appropriate to the problem, rather than a set of recipes with varying degrees of potential success. The information-gathering procedure can be adapted to a wide range of bioclimatic situations, because it deals with the basic processes controlling the availability of vital resources to biota.

Desertization: Irreversible Extension of Desert Land

Henry Noel LeHouérou

Functional and Evolutionary Ecology Center (CEFE), National Center for Scientific Research (CNRS), Montpellier, France

Abstract

Combating desertization first requires the discontinuation, or at least the serious mitigation of previous destructive activities that brought the situation about. Biological recovery may not be feasible anymore whenever degradation is extreme; artificial human-induced intervention may then be deemed necessary. On the other hand, in less extreme cases, artificial rehabilitation and restoration may be desirable to hasten the desired goal. Biological recovery may be achieved via centuries-old techniques of soil and water conservation, water harvesting, runoff farming, agroforestry, appropriate farming, stocking, range, and forest management. But such activities often necessitate a deliberate policy and adequate strategies of conservative land use; this, in turn, may require political and legal actions encouraging responsible land use management to achieve sustainability, i.e., a profound land reform. This has actually been achieved by various centuries-old peasant civilizations in various parts of the world arid lands.

INTRODUCTION

Desertization is the irreversible extension of desert-like landscapes and landforms to areas where they did not occur in the past.^[1,2] Desertization results, to a large extent, from land abuse by humans and livestock; it is not a consequence of climate fluctuation, albeit drought may worsen and accelerate a phenomenon that could have been triggered during high-rainfall periods (there are many examples of such seemingly paradoxical situations). It is estimated^[3–6] that over 20% of the 42 million km² of dry lands are submitted to a greater or lesser extent to desertization processes.

The causes of desertization are both direct and indirect. Direct causes^[3,7] are those that have a strong immediate impact on site soil characteristics and properties. The major one is the reduction of perennial plant cover and biomass that contributes to soil organic matter depletion. This reduction of soil organic matter content triggers a chain of actions and reactions affecting both soil and microclimate, leading to lowered biological activity, compacted soils with high runoff, and fast erosion processes, by both water and wind; soil may thus ultimately be turned sterile or almost so in a few years of abuse.

The indirect causes are those that bring about the depletion of natural resources, such as long-standing overcultivation, overstocking, poor farming practices, deforestation, destructive collection of fuel wood, and other mismanagement practices,^[1,2] and all these result from excessive and permanent pressure on the land by exceedingly numerous human and livestock populations: continuous high densities and stocking rates.

DEFINITION

Deserts are defined as regions where rainfed agriculture is not feasible because of excessive aridity.^[8] Unlike the word “desertification,” which has at least four distinct meanings, the term “desertization” is clearly defined. It implies irreversible extension of desert landforms and conditions to regions where they did not occur in the past.^[1,2] The desertization is primarily due to destructive human and livestock activities in arid environments. In spite of the United Nations Environment Programme (UNEP) Plan to Combat Desertification (as a follow-up to the United Nations Conference on Desertification (UNCOD) held in Nairobi in 1977, the Earth Summit of Rio de Janeiro in 1992, and the Convention of Paris in 1994), little has been done on a large scale, so desertization is likely to continue over the next years as it has in the past years.^[9]

FACTS AND FALLACIES

Origin of Deserts

Deserts are regions where, because of excessive aridity, no agriculture is feasible without supplemental irrigation.^[8,10] On the basis of their origin, there are five types of deserts.^[10,11] True climatic deserts result from general atmospheric circulation whereby the adiabatic subsidence of dried-up air masses occurs on the limits between the Ferrel and Hadley cells along the 30°N and 30°S parallels.^[11] The origin of true deserts varies with local conditions (e.g., tropical and subtropical deserts). Rain shadow deserts

(a particular case of climatic deserts) are formed due to orographic obstacles cutting the trajectory of rain-bearing frontal depressions (e.g., the Death Valley and Colorado River Delta east of the Sierra Nevada of California, Patagonia). Coastal deserts are formed due to the atmospheric stability resulting from the upwellings of coastal cold currents, such as along the Western continental shores of America and Africa (e.g., the Humboldt Current in Chile and Peru, the Benguela Current of Southwest Africa). Edaphic deserts result from geological and soil conditions that are inappropriate for agricultural activities and the development of natural vegetation, such as unweathered hard or toxic rocks, salinity, and alkalinity. Man-made deserts result from anthropogenic activities and destructive land abuse. This entry is concerned with the formation of the human-induced desert.

Fluctuations and Trends of Climatic Variables in Historical Times

Rainfall

There is a consensus among scientists on the absence of trends in long-term rainfall since the beginning of history.^[3,12–14] There is, however, evidence of considerable changes in the course of the Pleistocene and Holocene periods beginning 3000 and 10,000 years B.P., respectively, with some 10 alternating periods of dry and humid climates in the Sahara and Arabia.^[9,12,15,16] This evidence comes essentially from tree ring studies, pollen analysis, and lake-level fluctuations. Minor fluctuations took place, however, in the course of history such as the 25-year period of drought in the African Sahel (1968–1983) and East Africa from 1975 to 1984,^[15,17] in Chile from ca. 1900 to date, and in Argentina between 1900 and 1950.

Temperature

Variations in temperature are more complex to analyze. There is a consensus on a global increase of 0.5°C over the past 100 years.^[13,14] But this includes the effect of urbanization that may globally account for up to 0.2°C.^[18] Fluctuations during the historical period are fairly well documented. The causes of these “random” fluctuations are not known with any certainty. The magnitude of increase over the past 100 years is thus of the same dimension or smaller than previous random fluctuations.

Air Pollution

There is general agreement on the fact that the atmospheric content of carbon dioxide (CO₂) and other pollutants is increasing. The CO₂ content of the atmosphere was 280–300ppmv (parts per million in volume) at the beginning of the industrial era some 150 years ago.^[19] It is 370ppm, essentially due to the burning of fossil fuel.^[14] Similarly, the content of methane (CH₄) has doubled from 800 to

1750 ppbv (parts per billion in volume) over the same period.^[14] The main sources of CH₄ are swamps, rice fields, ruminants, forest fires, garbage disposal, oil industries, and termites.

But the situation is different in as much as it is the increasing content of CO₂ and CH₄ in the atmosphere that is causing a temperature rise, while in the past 160,000 years, and presumably all the quaternary, the situation was the opposite. It is the increase in temperature from orbital forcing that resulted in a rise of CO₂ and CH₄, by the oxidation of soil organic matter content, the melting of tundra permafrost soils, and the release of CH₄ from the thaw of frozen swamps. The undisputed 0.5°C/100 years of global temperature increase thus cannot, strictly speaking, be attributed to CO₂ or other atmospheric pollutants.

Land Surface Albedo

As vegetation is increasingly depleted and perennial plant cover recedes, the proportion of bare ground increases, enhancing its reflectivity, or the surface albedo.^[20] Higher albedo reduces temperature, decreases evaporation, and creates a thermic depression, impeding cloud formation and possibly decreasing rainfall. This so-called surface albedo feedback theory is, however, highly debated—actual facts have not, so far, proved it; rather the opposite.^[21,22]

DESERTIZATION

Definition

Desertization is the irreversible degradation of arid land resulting in desert-like landforms in areas where they did not occur in the past.^[1,2] This definition differs from the concept of desertification as accepted by UNEP in the 1977 UNCOD held in Nairobi.^[4,23] It was then defined as “land degradation under arid, semiarid, and dry subhumid climates that may ultimately lead to desert-like conditions.” The term “desertification” is used for two distinct meanings. It implies the *irreversible* degradation of arid lands, leading to the formation of man-made deserts. In Western Europe and European Economic Community, desertification is synonymous with land abandonment, resulting in natural reforestation and expansion of woodlands.^[24,25] Land abandonment may be referred to as “land desertion” because the rural population migrates to towns.^[25]

Causes of Desertization: Degradation Processes

The causes of desertization are both direct and indirect.

Direct causes

The direct causes pertain essentially to the destruction of the perennial plant cover and biomass and its consequences on soil characteristics through erosion, sedimentation,

waterlogging, and salinization.^[1,2,16,26–28] The destruction of perennial biomass and cover results in the following degradative chain reaction:

1. Reduced litter production and return to the soil particles decrease soil organic matter content.
2. Reduced soil organic matter weakens or destroys soil structure and aggregate stability.
3. Unstable soil aggregates increase surface soil sealing from raindrop splash on silty or loamy soils and biological crusting on coarse sandy soils.^[29]
4. Sealed soil surfaces increase runoff, decrease soil water intake and storage, and create a drier environment.
5. Increased runoff causes flooding; waterlogging; and mass die-off of shrubs, trees, and crops downstream and in closed depressions.
6. High wind speed on the soil surface, a consequence of reduced perennial plant cover, leads to higher albedo, increased potential evapotranspiration, increased water and wind erosion, and therefore drier microclimatic conditions.
7. Higher soil-surface daily maximum temperatures and therefore high evapotranspiration, due to the lack of shading, enhances the oxidation of soil organic matter, a rapid depletion of water reserves, and a shorter growing season. Lower soil-surface night temperature causes a larger diurnal and seasonal temperature range (thermal amplitude), leading to less favorable conditions for germination, emergence, and establishment of seedlings and to the restoration of the natural vegetation.
8. Decreases in the number, biomass, and activity of soil microflora (e.g., bacteria, actinomycetes, fungi, algae, and rhizospheric symbionts) as a result of decreasing organic matter content in the soil slow down nutrient turnover and reduce the availability of major and trace geobiogenic elements, leading to lower fertility and productivity.
9. Decreased productivity reduces the number, biomass, and activity of soil microfauna, mesofauna, macrofauna, and megafauna.
10. Wind erosion (creeping, saltation, suspension, and corrosion) results in the development of desert pavements (regs, serirs, hamadas, and gobis), rock mushrooms, and yardangs.
11. Wind deposition leads to the formation of sand clay dunes (lunettes), loess, nebkas, ramblas, shamo, ergs, edeyen, nefuds, sand sheets, and sand veils. Gravity erosion leads to dry colluvium deposits.
12. Water erosion (sheet, rill, gully, pipe, landslides, etc.) leads to flooding, sedimentation, and alluvium deposition.
13. Rising water tables and salinity result from higher runoff and lesser pumping by shrubs and trees.
14. Rising salinity and soil sterilization are caused by poor drainage and other mismanagements.

Indirect causes

The indirect causes of desertization are those that exacerbate the development of the direct causes.

1. Rapid human population growth and quick increase in population density lead to high human and livestock pressure on the land. The human population in the arid lands of the developing countries has grown at an annual rate of 3.2% since 1950.^[2,3,16,30]
2. Livestock populations in Africa and Southwest Asia have increased at an average annual rate of 2.2% since 1950.^[3,12,16]
3. Soil degradation is accentuated by overcultivation, inappropriate farming methods, poor land management (e.g., cultivation of land that is too dry, too steep, and too shallow), inappropriate tillage (up and downhill plowing), quasi-exclusive utilization of disc plows, inappropriate crop rotation patterns, inadequate field size, careless harvesting, postharvesting land management, etc.
4. Deforestation is exacerbated by excessive collection of firewood (1.5 kg per person per day). As arid land steppe vegetation of dwarf shrubs bears some 300–600 kg dry woody matter per hectare, each person depending on this type of fuel destroys about 1 ha of steppe vegetation per annum.^[8]
5. Overcollection of medicinal and other useful plants contributes to the decline of plant cover and biomass.
6. Wildfires are particularly harmful in the tropical savannas. As they occur in the dry season, they leave a soil surface that remains bare and therefore vulnerable to erosion during the next rainy season.^[17,31]
7. Vegetation arcs are particular patterns of distribution, whereby plants are concentrated on contour strips alternating with bare and sealed interstrips. Seen from above, as on air photos or satellite images, the land looks like a tiger skin, hence the expression of “tiger bush.”^[17,24,27] This is a case of edaphic aridity when, owing to the thinning of vegetation from woodcutting and/or overbrowsing and the consecutive runoff and erosion, the soil moisture regime is too low for the vegetation. Thus, vegetation is confined in strips that permit higher soil moisture due to run-on.
8. Inadequate legislation or lack of enforcement of legislation on land use and erosion control measures.
9. Inappropriate land-ownership systems under which land, grazing, and water are free communal resources while livestock are privately owned. Thus, it is in each stockman’s interest to draw the maximum from the common resource without investing anything in it, the “tragedy of the commons.”
10. Inappropriate marketing facilities and inadequate incentive to de-stock and cull animals.
11. Poverty and lack of education and inefficient extension services.

Table 1 Desertization risk assessment from perennial plant canopy cover evaluation.

MAR nmm	Perennial plant canopy projection cover in percent of ground surface					
	0–1	1–5	5–15	15–25	25–50	>50
50–100	5	5	4	3	2	1
100–200	5	4	3	2	1	0
200–300	4	3	2	1	0	0
300–400	3	2	1	0	0	0
400–500	2	1	0	0	0	0
500–600	1	0	0	0	0	0

Note: 0, present hazard non-existent or very low; 1, immediate risk low; 2, immediate hazard moderate; 3, immediate risk serious; 4, immediate hazard severe.

Source: From Le Houérou.^[33]

Diagnosis and evaluation of desertization

Desertization may be evaluated via various criteria, namely measuring soil erosion and sedimentation, assessing perennial plant canopy cover and biomass or the basal cover of perennial species, and evaluating the rain-use efficiency (RUE = kg DM/ha/yr/mm) and computing the production to rain variability ratio (PRVR = CV Ann. Prod./CV Ann. rainf.).^[32] The evaluation of RUE is a particularly easy, quick, and clean method.

Low perennial plant cover is the principal factor of soil surface erosion by water and wind. In the Mediterranean steppelands, there is virtually no soil surface erosion when perennial plant canopy cover reaches 25% of soil surface. In such cases, erosion is compensated by deposition and sedimentation.^[26] In the North African steppes, for instance, each 1% of perennial canopy cover corresponds to a biomass

of 30 to 60 kg DM/ha.^[33] It is then easy to determine the stage of degradation and desertization from the evaluation of perennial plant canopy cover (Table 1). The world regional distribution of arid lands is shown in Table 2.

Severity and Extent of Desertization

Can desertization occur without the impact of drought?

True climatic deserts cannot exist without permanent and extreme climatic aridity. But such is not the case with the occurrence and spread of man-made deserts. Contracted vegetation occurs in all world deserts with a mean annual rainfall (MAR) isohyets of between 50 and 150 mm depending on the substrate, the anthropogenic impact, and other local factors [e.g., high atmospheric humidity and occult precipitation, or, conversely, continentality, low RH, and high precipitation to potential evapotranspiration ratio (PET)]. Desertization is often caused by droughts, but the primary causes have often been operating long before drought occurred. The effects may have been hidden by a period of better than average climatic conditions. This was the case in the West African Sahel.

The analyses of available information lead to the following conclusions:

1. Desertization may be triggered during non-drought periods.
2. Desertization cannot result from drought alone.
3. The main causative factor appears to be land mismanagement from excessive anthropogenic pressure on the land (land abuse), beyond the ecosystems' resilience.

Table 2 Regional distribution of world arid lands.

Geographic area	Continental distribution (10 ³ km ²)					% ^a	
	Eremitic	Hyperarid	Arid	Semiarid	Total		
MAR (mm)	<50	50–100	100–400	400–600

Source: From Oldeman, Hakkeling, et al.^[5] and Middleton & Thomas.^[6]

Severity and extent

The global extent of land degradation has been assessed by International Soil Reference and Information Centre/UNEP.^[4–6,23] The conclusions are in good agreement with other independent studies.^[3] Tables 3, 4, and 5 show that overstocking and overgrazing are the major causes of arid land degradation worldwide, followed by overcultivation and poor farming methods. The regional and local causes, however, may considerably alter this pattern. Overcultivation and shrubland clearing, for instance, are by far the prime causes in Northern Africa, Southwestern Asia, and Northwestern China, while overgrazing is the foremost cause in the Sahel, East Africa, North and South America, and Australia (Table 5). Salinization affects 1.5 million hectares annually out of a world irrigated land area of 2 million km². The total area lost to secondary salinity over the 20th century is about 25 million hectares.^[3,32]

Natural Amelioration

Natural amelioration of land management to restore or rehabilitate ecosystems and environment implies the elimination or substantial reduction of the causes that leads to degradation. This goal can be achieved by reducing stocking rates to carrying capacity; restricting farming to appropriate areas, such as depressions with deep soils benefiting from runoff or having a water table; and improving grazing systems through the control of livestock, fencing, rotational/controlled grazing, and installing temporary exclosures. These activities are usually cheap and efficient tools for restoring and rehabilitating arid lands.^[34–36]

Managed Restoration

Human-assisted rehabilitation includes a large array of techniques from the simplest and cheapest to the most sophisticated and costly but not necessarily efficient.

Surface roughness

Techniques to create surface roughness break the surficial crust (e.g., a silt seal or a biological crust), increase permeability to air and rainwater, and facilitate seed germination and seedling emergence. A simple technique for breaking crust involves spreading branches from spiny trees and shrubs on the soil surface (*Acacia* spp., *Balanites* spp., *Ziziphus* spp., *Prosopis* spp., *Rhus* spp., *Parkinsonia* spp., *Commiphora* spp., etc.). Soil surface roughening may also be achieved with the plow harrow, hoe, cultivator, subsoiler, ripper, basin lister, etc.^[17]

Contour lining

This may be achieved by using stones or pieces of hardpan or duricrusts (e.g., gypsic pans, calcrete, iron pans, or lateritic pans). Light contour lining aims at reducing sheet erosion and improving water intake. It may also be achieved via mechanical equipment used for terracing and building contour banks, contour benches, or ditches.

Ripping and subsoiling

These techniques use heavy equipment to break deep, hard lime, gypsum, silicium (silcrete), or iron pans or to loosen hard compacted soils to improve water intake and storage

and deepen the root zone of protective plants, particularly shrubs and trees.

Termite-assisted hand-pitting across a surficial pan

The southern Sahelian technique of the “Zai” is a cheap and efficient practice. It involves digging pits (40 length × 40 width × 15 depth) about 80 cm apart at a density of 2500 pits/ha. These pits are dug a few months prior to the onset of the rainy season, and 1000–1500 kg/ha of organic matter (e.g., litter, straw, and stovers) is placed at the bottom of these pits. The organic matter attracts termites that dig deep galleries below the pan. The microenvironment thus created is then manured at a rate of 1000 kg/ha of dry corral dung. Pearl millet or sorghum planted in these pits may reach maturity even in a dry year, owing to the better soil water regime. Each pit is a green island amid a devastated environment landscape, and the beneficial effect may last up to 30 years. The cost of making Zai is 150–300 human-days per hectare for a pit density of 2500/ha, 1000 kg of organic matter, and 1000 kg of corral manure.^[38]

Table 6 World areas under agroforestry management.

Fodder cacti	1,200,000 ha	North Africa, South Africa, North and South America
Saltbushes	1,000,000 ha	North Africa, South Africa, Southwest Asia, North and South America, Australia
Acacias spp.	600,000 ha	North Africa, Sahel, South Africa, Australia
Prosopis spp.	50,000 ha	North and South America, India
Agave americana	100,000 ha	South Africa
Miscellaneous (Saxaouls, Tamarix, Bohemia olive, and poplars)	250,000 ha	Africa, Australia, North and South America, Europe, Central Asia

Range reseeding

Range reseeding and establishing improved pasture are also feasible in the semiarid zone, but not so in the arid zone.^[7,28]

Agroforestry

Agroforestry is practiced on 3.2 million hectares in world arid lands. Agroforestry, using either native or exotic species, is a very potent and efficient tool for biological recovery, allowing productivity 3 to 10 times higher than that of pristine vegetation under the same ecological conditions. These lands are distributed as shown in Table 6.^[35,36]

Wildlife management, wildlife husbandry, and tourism

Wildlife management and husbandry are actively pursued in an increasing number of arid land countries: namely the United States, Australia, East Africa, Southern Africa, New Zealand, Argentina, and Western Europe. Privately owned game ranches or game farms are quickly developing in Africa.

Adaptive arid land strategy and sustainable development policies

Mitigating desertization is a problem of sustainable arid land development. Sustainable development policies include many facets (e.g., technical, social, economic, political, legislative, organizational, and educational). An important step toward sustainable development is reforming the land tenure system. This would require a fundamental land reform in order to shift from communal or tribal land ownership to secure private systems, whereby long-term investment becomes possible and long-term planning can be implemented.

Developing Countries: Economics of Soil Management

Stefano Pagiola

Environment Department, World Bank, Washington, District of Columbia, U.S.A.

Abstract

Land degradation problems seem unlikely to cause the catastrophic agricultural declines as some fear, but they can have acute consequences at the local level, particularly for poor farmers. Farmers have strong incentives to respond to the on-site effects of soil degradation, and the evidence shows they often do so. The changing understanding of farmers' incentives to undertake appropriate soil management practices has shifted the emphasis of interventions away from top-down projects focusing on technical solutions. Overall policy reform is seen as a necessary precondition for any intervention. Where on-site effects dominate, participative projects, in which responses appropriate to local conditions are developed in collaboration with the affected land users, have come to play an important role. Where off-site effects dominate, efforts have turned to the development of systems of payments for environmental services.

INTRODUCTION

Agriculture plays a vital role in the economies of developing countries and in the welfare of their populations, including many of their poorest members. Inappropriate soil management is thought to threaten the sustainability of agricultural production by undermining the soil resource base on which agriculture depends.^[1–4] Developing country farmers often have limited capacity to substitute fertilizers and other inputs for soil fertility, making the problem particularly acute. Addressing such problems is not easy, however, because decisions about soil management are made not by governments, but by individual land users according to their own priorities and constraints. Economic analysis of soil management problems in developing countries has focused increasingly on understanding why farmers use soils in the way they do, and in particular on understanding their reasons for not using them sustainably.

ASSESSING THE PROBLEM

Soil has value because of its role in crop production. Cultivation, however, can damage the soil. For example, clearing vegetation cover exposes soil to water and wind erosion; repeated tillage weakens soil structure; crop production removes nutrients; and use of machinery leads to soil compaction. The economic impacts of land degradation can be divided into on-site and off-site effects. On-site degradation can result in lower yields (and, hence, lower revenues) or in the need for higher input levels (and, hence, higher costs) to maintain yields.^[5] Off-site degradation can cause problems such as sedimentation and changes in hydrological flows.^[6,7] Adverse off-site effects can also occur in the absence of on-site effects (e.g., if

agrochemicals contaminate water supplies). Land degradation has also been seen as contributing to global problems, such as climate change, by reducing soil's ability to store carbon.^[8,9] On-site problems have usually been thought to be most important in developing countries,^[10] although attention has been focused on off-site effects, particularly in Asia and Latin America.^[11]

Assessing the absolute and relative magnitude of soil degradation and its consequences is difficult. Valuing on-site effects is straightforward in principle, but it has proved empirically difficult in practice, because of the lack of appropriate data, particularly on the yield impact of degradation. The site specificity of soil management relationships limits the applicability of data collected in one location to analysis of problems at another. Efforts to value off-site effects are also constrained by insufficient data, exacerbated by unclear cause-and-effect relationships between events that are widely separated in both space and time.^[12] In sub-Saharan Africa, estimated annual on-site losses from degradation range from under 1% of agricultural gross domestic product (GDP) in Madagascar, Mali, and South Africa, to as much as 8% in Zimbabwe.^[13] Three different studies of Ethiopia, however, showed estimated annual losses of less than 1%,^[14] 4%,^[15] and 5%^[16] of agricultural GDP, demonstrating the weakness of the data and the dependence on the assumptions made.

Although data weaknesses make it difficult to arrive at strong conclusions, fears of catastrophic damage from soil degradation do not appear to have been realized. A review of 26 global and regional studies and 54 national studies concludes that degradation is not likely to threaten aggregate global food supply by 2020, although degradation problems can be acute at the local level.^[4] An analysis of degradation problems in El Salvador, e.g., concludes that, while the oft-cited estimate that “75% of the country is

degraded” is almost certainly exaggerated, degradation does affect about one-third of farm households—a significant social problem by any standard.^[17]

UNDERSTANDING FARMER BEHAVIOR

Because farmers adopt soil management practices that degrade the soil, many researchers have concluded that farmers are ignorant or tradition bound. Beginning with the work of Schultz,^[18] however, it has been increasingly recognized that developing country farmers are, in fact, rational decision makers.^[19,20] Research demonstrates that they are quite aware of the properties and behavior of their soils and of the problems that inappropriate soil management can cause.^[21–25]

Farmers experience the effects of any on-site problems directly, so they generally have a direct incentive to respond to them. But even though sustainable practices may bring long-term benefits, they can also be costly, both directly, in terms of investment requirements and maintenance costs, and indirectly, in terms of forgone production. The critical question farmers face is whether the long-term benefits of sustainable practices make these costs worth bearing. In many cases, the answer is clearly yes. Almost all farmers in the Kitui/Machakos area of Kenya, e.g., have adopted some form of conservation practice,^[26,27] while small-scale farmers in El Salvador have done so on over one-half the fields on moderate and steep slopes.^[17] In some instances, however, the costs of adopting particular conservation techniques exceed the benefits. Analysis of conservation measures in six Central American and Caribbean countries, e.g., found that many measures promoted by conservation projects had negative returns from the farmers’ perspective.^[28]

Many factors can affect the profitability of conservation measures from the farmers’ perspective. These include the rate and severity of damage to the soil, the consequent effects on productivity, the value of lost production (for sale or subsistence consumption), the extent to which fertilizers and other inputs can cost-effectively substitute for lost fertility, the effectiveness of available conservation measures and their costs, including initial investment and maintenance, the relative riskiness of production, with and without conservation, and the farmers’ own preferences, including—crucially—their preference for present as opposed to future consumption (i.e., their discount rate).^[27–30] Because all of these factors can vary substantially, even in small areas, it should not be surprising that the extent of adoption of conservation measures also varies substantially. Adoption can also vary over time: When initial productivity losses are small, it makes sense to delay adopting conservation practices until later.^[31,32]

Poverty is often thought to play a significant role in conservation adoption decisions of developing country farmers, by causing them to emphasize short-term over long-term benefits and limiting their ability to undertake

investments.^[33,34] Conversely, it has been argued that poorer farmers may have greater incentives to conserve soil than better-off farmers, because they face greater penalties for failing to do so.^[35] Empirically, one can also observe that poor farmers do often undertake a variety of long-term investments—in livestock, tree crops, the education of their children, and other assets with long-term returns. Thus, in the case of Kitui/Machakos, even expensive conservation measures such as terraces have been widely adopted by poor farmers, who lack access to formal credit markets.^[26,27] Like many other aspects of the soil-conservation debate, the exact role played by poverty is likely to vary from case to case.

Government policies can often affect the perceived incentives to adopt conservation practices. Many developing countries’ policies discriminated heavily against agriculture,^[20,36] making investments in agriculture, including conservation investments, less attractive. The policy environment has been identified as the main cause of degradation, e.g., in Colombia.^[37] The relationship between government policies and conservation is complex, however, and could go in either direction depending on the details of the policy and the specific conditions encountered at any given site.^[38,39] By keeping prices low, e.g., Kenyan maize price policy tended to reduce returns to conservation in Kitui/Machakos, and thus discourage its adoption, but even in that area the opposite effect was also observed.^[39]

Institutions often play a critical role in conservation decisions. A key institutional factor is the security of rights to land. Given the long-term nature of conservation investments, incentives to undertake them will be lower, if farmers fear losing their land.^[40,41] Lack of titles is not, however, always synonymous to tenure insecurity. A substantial literature demonstrates that many traditional African land tenure systems do not result in tenure insecurity, even in the absence of titles.^[42] Institutions can also play other roles. In Kitui/Machakos, women’s labor exchange groups (mwethya) substituted for missing credit markets and allowed farmers to undertake costly conservation measures.^[27]

When the effects of soil degradation are felt primarily off-site, the situation is very different. Because these problems affect others rather than themselves, farmers have no incentive to address them. Many soil conservation projects have been motivated by the desire to protect downstream infrastructure, such as dams, from the effects of upstream degradation. Because the practices promoted by these projects are not necessarily profitable from the farmers’ perspective, their success rate has been very low.^[43] Subsidies and/or compulsion can sometimes lead to temporary adoption of the measures being promoted, but they tend to be rapidly abandoned once the project is completed.^[28,44]

CONCLUSION

Land degradation problems seem unlikely to cause the catastrophic agricultural declines as some fear, but they can

have acute consequences at the local level, particularly for poor farmers. Farmers have strong incentives to respond to the on-site effects of soil degradation, and the evidence shows they often do so. The changing understanding of farmers' incentives to undertake appropriate soil-management practices has shifted the emphasis of interventions away from top-down projects focusing on technical solutions. Overall policy reform is seen as a necessary precondition for any intervention. Where on-site effects dominate, participative projects, in which responses appropriate to local conditions are developed in collaboration with the affected land users, have come to play an important role. Where off-site effects dominate, efforts have turned to the development of systems of payments for environmental services.

Diagnostic Horizons

E.M. Bridges

*International Soil Reference and Information Centre (ISRIC), Wageningen,
the Netherlands*

Abstract

The use of diagnostic horizons, focused on observable and measurable soil morphology, rather than ill-defined genetic processes, helped greatly in reaching agreement for the World Reference Base as a single international system of soil classification. In both theory and practice, it has been one of the most useful developments in soil classification.

INTRODUCTION

In layman's terms, the concept of topsoil and subsoil is widely understood, but pedologists have built upon this idea and given it a scientific basis, using the term soil horizons for these layers of soil. A soil horizon may be defined as a layer of soil lying approximately parallel to the earth's surface, having pedological characteristics. A soil profile includes the collection of soil horizons revealed in a section of the soil downward from the surface. As soil horizons develop by means of the processes of soil formation acting upon weathered geological materials, they are often referred to as genetic horizons. The definition of these genetic horizons was effectively qualitative in approach, reflecting a perceived means of genesis. Toward the end of the 19th century and throughout the first part of the 20th century, various systems of nomenclature arose in different countries allocating letters O, A, B, C, etc. to genetic horizons, but their use was not uniformly applied and so they became discredited in the eyes of some authorities. Such shorthand designations are "an interpretive symbol," based upon horizon morphology and implied genesis that are used to identify and label a soil horizon.^[1] In the United States, as demonstrated by Soil Survey Staff,^[2,3] certain organic O horizons and mineral A, B, and C horizons were designated master horizons and were in vogue for the description of soil profiles. A similar system was developed in the then Soviet Union as described in *Pochvennaya Syemka*,^[4] and many other countries followed their example. Although the ABC system of labeling worked reasonably well in the areas where it developed, e.g., Russia and the United States, soil scientists working in tropical areas, where soils had a longer and more complex history of development, found it difficult to use,^[5,6] who strived to develop systems of their own. Prior to the 1960s, the presence of certain horizons was essential for the classification of soils; Podzols, e.g., had to possess a bleached horizon and below it a horizon of accumulation of organic matter, iron, and aluminum, and gley soils had to have the features of hydromorphism. As

the definitions of soil horizons in the early 20th century were cast in general, rather than in specific, quantitative terms, there were overlaps and gaps that caused confusion in the recognition of taxonomic units employed in soil classification systems.

The idea of diagnostic horizons first appeared in the 6th Approximation of 1957,^[7] when the earlier concept of soil horizons was taken and developed into a basis for the quantitative identification of horizons and their unambiguous incorporation into systems of soil classification.

DIAGNOSTIC HORIZONS IN THE U.S. DEPARTMENT OF AGRICULTURE SOIL TAXONOMY

From 1951, soil scientists in the United States began to develop a new approach to soil classification and after a number of preliminary drafts, the 7th Approximation was published as a discussion document. In this approach to soil classification, named diagnostic horizons were selected as a key to the classification system. Originally, 6 surface diagnostic horizons, called epipedons, and 12 subsurface diagnostic horizons were proposed. Although the conceptual basis of what was a diagnostic horizon or how it was chosen were not defined or described, it amounted to a soil horizon or a group of closely related horizons that possess a set of quantitatively defined properties. By fulfilling their criteria, and with the use of a key, soils may be placed in their correct position in one of the 10 orders of the system.

The quantitative definition of these diagnostic horizons is such that they cannot be related in all cases to the master horizons of other systems of genetic horizon designation. In discussion about the development of the Soil Taxonomy system, Smith^[7] explained that the concept of master horizons and the ABC system was not used in Soil Taxonomy because of a lack of agreement about its use among pedologists. Therefore, he adopted the diagnostic horizon concept, which did not carry with it any inherited controversy.

Table 1 Diagnostic horizons of the USDA 7th Approximation.

Epipedons	Subsurface horizons	Other horizons
Mollic	Agric, albic, anthropic, and argillic	Calcic
Umbric	Cambic	Gypsic
Histic	Natric	Salic
Ochric	Oxic	Pans: duripan and fragipan
Plaggen	Spodic	

Source: From Soil Survey Staff.^[8]

The diagnostic horizons proposed in the 7th Approximation are presented in [Table 1](#).

Since its publication in 1975, Soil Taxonomy has been continually updated and improved through correlation meetings and advice received from soil scientists around the world. As a result, two new epipedons have been introduced: a melanic epipedon to provide for the surface horizons of soils on tephra and volcanic glass and a folistic epipedon to provide for organic soil materials, saturated for more than 30 days and consisting of more than 75% sphagnum. Six of the subsurface diagnostic horizons that first appeared in the 7th Approximation remain with improved definition in Soil Taxonomy. These are the agric, argillic, cambic, natric, oxic, and spodic horizons, together with horizons referred to as pans: duripan and fragipan. “Other horizons” that have persisted throughout the development of Soil Taxonomy are the calcic, gypsic, and salic horizons. New horizons that have been introduced are the glossic (to provide for degraded argillic), kandic, and natric horizons; the kandic has been introduced to provide for a more clayey subsurface horizon with an apparent cation exchangeable capacity of 16 cmol or less per kg of clay; orstein has been separated from the spodic horizon, and placic has been introduced for thin iron pans. Petrocalcic and petrogypsic have been introduced for carbonate and gypsic-cemented horizons, respectively. Sombric caters for dark-colored, freely drained subsurface horizons with illuvial humus. Additionally, there is a sulfuric horizon with a low pH and containing jarosite. Other diagnostic soil characteristics, e.g., slickensides and lamellae, and soil conditions, e.g., andic soil properties, are strictly defined. Full definitions of all these horizons and characteristics are given in Soil Taxonomy,^[9] and summaries are provided by Tiurin et al.^[10] and in various textbooks. Since the development of Soil Taxonomy, the concept of diagnostic horizons has been widely used as the basis of several national systems of soil classification (e.g., Brazil and South Africa) and in the legend for Food and Agriculture Organization (FAO).^[11]

REFERENCE HORIZONS OF FITZPATRICK

In parallel with developments in the United States, FitzPatrick,^[12–14] independently proposed a system of

Table 2 Reference horizons proposed by FitzPatrick.

classification with a greater number of defined horizons, called reference horizons. The soil is viewed as a 3-D continuum, whereas a soil profile is in reality only a 2-D section through the soil. As the soil reflects the conditions in which it was formed, most importantly the effects of climate, parent material, and relief, a pattern of soils occurs over the landscape that is 3-D. The boundaries between soils are rarely abrupt, but are zones of gradual change. Thus, it is necessary to consider soils as 3-D entities that vary in space and time. Within this 3-D system, both conceptual space and observed field characteristics are accommodated in reference segments where there is a single unique dominating property or combination of properties formed principally by a single set of processes. Intergrade segments contain properties that gradually change between two reference segments. Within each segment, it is possible to recognize reference horizons, intergrade horizons, compound horizons, and composite horizons. The reference horizons proposed are presented in [Table 2](#).

THE FAO–UNITED NATIONS EDUCATIONAL, SCIENTIFIC AND CULTURAL ORGANIZATION (UNESCO) SOIL MAP OF THE WORLD LEGEND

The FAO–UNESCO Soil Map of the World was completed during the decade 1971–1981^[11,15] with the aim of making a first scientific appraisal of the soil resources of the world, providing a basis for transfer of knowledge, and promoting a generally accepted system of soil classification, especially

Table 3 Diagnostic horizons used in the legends of the Soil Map of the World.

for educational, research, and development activities. Following the use of diagnostic horizons in Soil Taxonomy, a similar limited number of horizons with measurable and observable properties were employed by the editors of the 1974 legend of the Soil Map of the World (Table 3).

Reflecting the increasing impact of human activity in modifying, in particular, the A horizon of soils, a fimic A horizon was added in the 1988 revision to provide for horizons with a man-made surface layer with a thickness of 50 cm or more, produced by long continued manuring with earthy mixtures. It commonly contains artifacts such as brick and pottery and includes the plaggen epipedon and the anthropic epipedon of the Soil Taxonomy system. The difficulties, which had been experienced in the field, especially in tropical regions, where oxic and argillic horizons were difficult to separate, resulted in a redefinition into the argic and the ferrallic B horizons, respectively. The petrocalcic and petrogypsic phases became diagnostic horizons and other definitions were amended, but calcic, gypsic, histic A, mollic A, ochric A, spodic B, sulfuric, and umbric A horizon definitions were unchanged. As with the system of Soil Taxonomy, a number of diagnostic properties, which are not considered as horizons, are also used in the definitions of the diagnostic horizons. These refer to andic soil material and ferralitic, ferric, fluvic, hydromorphic, nitric, and vertic properties. With their sets of quantitatively defined properties, produced by the soil-forming processes, the use of diagnostic horizons has made it possible to base a classification on general principles of soil genesis but objectivity was retained because the processes themselves are not used as criteria, only their effects expressed in terms of morphological properties, which have measurable values.

THE WORLD REFERENCE BASE (WRB) OF THE INTERNATIONAL UNION OF SOIL SCIENCES

Within the international community, it has long been appreciated that there has not been a generally accepted system of soil classification. In 1982, the International Society of Soil Science initiated the program to develop an international reference base for soils, but it languished until 1992. In that year, the decision was taken to make a WRB by

developing the revised (1988) FAO–UNESCO legend for the Soil Map of the World.^[16] In this way, advantage could be taken of the international correlation work that had taken place since the Soil Map of the World had been published.

The objectives of WRB were to develop the FAO–UNESCO map legend into a comprehensive, internationally acceptable system for delineating soil resources and to provide a sound scientific basis to support it. The WRB is based upon morphological characterization of soils and is supported by laboratory analyses where necessary. Its authors claim that it provides an easy means of communication about soils, including the transfer of data and technology relevant to soils both for soil scientists and for related environmental fields. As with other soil classification systems, it purports to show the relationships within and between the different soils of the world.

WRB adopted the use of diagnostic horizons as reflecting the results of widely recognized processes of soil development and improved the FAO definitions in terms of morphological characteristics and/or analytical criteria. Of the 16 diagnostic horizons of the 1988 FAO–UNESCO revised legend, the fimic A horizon has been discarded and replaced by hortic, plaggic, and terric horizons, respectively. The histic horizon has been broadened as its minimum thickness has been reduced to 10 cm and has been used to define Histosols. Experience with Chinese soils has shown that the former P₂O₅ requirement for the mollic and umbric A horizons of the revised FAO–UNESCO system is untenable as a criterion. The unique properties of Chernozems were not effectively reflected in the definition of the mollic A horizon, and so a chernic horizon has been introduced for the deep, blackish, porous surface horizons typical of Chernozems. Increasing the percentage of clay skins from 1% to 5% on both horizontal and vertical ped faces and pores is expected to give an improved correlation between field and micromorphological evidence.

The cambic horizon has always suffered from being a negative concept, without many pedological criteria. Its positive points such as depth, texture, structure, color, and the presence of weatherable minerals have given it a more positive image. In the case of the spodic horizon, it has been supplemented with the 1996 developments in Soil Taxonomy. In addition to the diagnostic horizons mentioned, additional 19 new horizons have been proposed. Full list is given in Table 4 and in the WRB for Soil Resources.^[17,18]

The adoption of the concept of diagnostic horizons by U.S. Soil Survey Staff has led to their acceptance in systems of soil classification in many countries of the world. Subsequent refinements and work for the WRB indicate the necessity for a greater number of diagnostic horizons to cover the nature and range of soil morphological features.

Table 4 Diagnostic horizons of the WRB for Soil Resources.

Albic	Ferric	Mollic	Salic
Andic	Folic	Natric	Spodic
Anthraquic	Fragic	Nitric	Sulfuric
Argic	Fluvic	Ochric	Takyric
Calcic	Gypsic	Petrocalcic	Terric
Cambic	Histic	Petroduric	Umbric
Chernic	Hydragric	Petrogypsic	Vertic
Cryic	Hortic	Petroplinthic	Vitric
Duric	Irragric	Plaggic	Yermic
Ferralic	Melanic	Plinthic	

Source: From FAO^[17] and ISSS Working Group RB.^[18]

The use of diagnostic horizons, focused upon observable and measurable soil morphology, rather than ill-defined genetic processes, helped greatly in reaching agreement for the WRB as a single international system of soil classification. In the revised legend for the Soil Map of the World,^[16] it is stated that the use of diagnostic horizons has proved to be most appropriate. In both theory and practice, it has been one of the most useful developments in soil classification.

Diffusivity: Measurement

Toru Nakajima

Department of Agriculture, Meiji University, Kawasaki, Japan

Abstract

Soil gas diffusion is important for understanding many processes in the interchange of gases between soil and the atmosphere. The Currie method, using a soil core sample, is the most widely used method for determining the soil gas diffusion coefficient (D_p/D_0). The choice of the method depends on available apparatus, cost, precision, and advantages of the methods. Modeling transport of gas movement in soil requires knowledge of the gaseous diffusion coefficient. Numerous models of soil gas diffusion using soil properties have been proposed. Empirical models vary for types of soil materials and ranges of soil air content used in their development.

INTRODUCTION

Diffusion of gases [e.g., oxygen (O_2), carbon dioxide, methane, and nitrous oxide] through the soil has far-reaching implications on soil biota and gaseous emissions. For instance, plant roots and soil microbes need O_2 for respiration which can be quickly depleted in the soil and must be replenished with O_2 from the atmosphere. Gaseous movement in soils is mainly driven by the diffusion processes associated with differences in gas concentration gradients,^[1] soil physical properties (e.g., soil texture, clay mineral, macro and micro pores, bulk density, total porosity, aggregation, and pore size distribution), and moisture conditions.^[2] Further, gaseous diffusion depends on the continuity of soil porous media through the gas exchange process, more directly than any other soil physical properties.^[3] Therefore, the principle of gaseous movement in soils must be well understood to optimize the potential of agricultural practices and to reduce emissions of greenhouse gases. This entry describes a simple laboratory method using a soil core sample for measuring soil gas diffusion coefficients.

PRINCIPLES AND EQUATIONS

Molecular gas diffusion in soils can be described by Fick's law for steady state:^[1]

$$F_g = -D_p \frac{\partial^2 C_g}{\partial x^2} \quad (1)$$

where F_g is the gas flux density ($g\ m^{-2}\ s^{-1}$), D_p is the soil gas diffusion coefficient ($m^2\ s^{-1}$), C_g is the gas concentration in the gaseous phase ($g\ m^{-3}$), and x is the distance (m soil). For non-steady-state condition, gas diffusion in soil can be described by combining the continuity equation (conservation of mass) with Fick's first law (Eq. 1).^[1]

$$\epsilon \frac{\partial C_g}{\partial t} = D_p \frac{\partial^2 C_g}{\partial x^2} \quad (2)$$

where ϵ is the soil air content ($m^3\ m^{-3}$) and t is the time (s). Because D_p is significantly affected by temperature and atmospheric pressure, the relative gas diffusion coefficient (D_p/D_0) defined as the ratio of the soil gas diffusion coefficient to that in free air is used. The D_0 is the gas diffusion coefficient in free air.

MEASUREMENT OF SOIL GAS DIFFUSION COEFFICIENT

Gaseous diffusion in soil under laboratory conditions is measured by the Currie method^[4,5] (Fig. 1). The device for this method consists of two main parts: the diffusion chamber and soil sample holder. The diffusion chamber has an O_2 concentration sensor and inlet and outlet ports for injecting nitrogen (N_2) gas in and venting the chamber gas out. The O_2 concentration is measured by the O_2 sensor (e.g., Model KE50; Figaro USA Inc., Illinois, U.S.A.) and is recorded with a data logger (e.g., Model DI-710; DATAQ Instruments Inc., Ohio, U.S.A.) for duration of the soil gas diffusion measurement. The soil sample holder is located above the diffusion chamber with the bottom of the soil sample facing the diffusion chamber. In order to achieve an airtight seal between the sample and the diffusion chamber, O-ring rubber and silicon oil are used. The diffusion chamber is initially flushed with 100% N_2 , and the O_2 concentration is measured in the diffusion chamber in order to monitor the intake rate of atmospheric O_2 through the soil sample. The time rate of O_2 change of concentration in the chamber is determined and related to the soil gas diffusion coefficient. In general, the tracer gases for soil gas diffusion measurements are N_2 and O_2 because of ease to obtain and treat, and the possibility to be easily detected by sensor. However, when O_2 is used for experiment, the experimental time should be

Fig. 1 (a) Photograph and schematic diagram of the device and (b) design used for measuring the soil gas diffusion coefficient of a soil core sample.

preferably short to minimize O₂ consumption by soil respiration. The choice of the method must depend on available apparatus, cost, precision, and advantages of the methods related to the goal of the study.

PREDICTIVE EQUATIONS FOR SOIL GAS DIFFUSION COEFFICIENT

Since measurement methods are time consuming, costly, and often not available, many gas diffusion empirical models have been developed for predicting gaseous diffusion. To predict soil gas diffusion coefficient from soil properties (e.g., soil air content, total porosity, and water retention parameter), several models are proposed (Table 1). One of the earliest attempts to describe the soil gas diffusion was by Buckingham.^[6] Numerous studies were conducted on model development during the first half of the 20th century,^[5,7,8] and a considerable progress was made.^[11,14,15] Models outlined in Table 1 vary in their approach and for use on type of soil materials and range of soil air content used for their development.^[16] Several models listed in Table 1 are widely used in numerical simulations; however, they are sensitive to error at different levels in the input parameter. In addition, there is no obvious *a priori* best relationship for a soil. Comparison of data obtained by different models is shown in Fig. 2.

CONCLUSION

This entry describes a Currie method using a soil core sample for measuring soil gas diffusion coefficients (D_p/D_0). The choices of the method depend on available apparatus, cost, precision, and advantages of the methods. Numerous models of soil gas diffusion using soil properties have been proposed. In this entry, the comparisons of relative soil gas diffusion coefficient by different models are

Table 1 Predictive equations for the soil gas diffusion coefficient.

Model	References	Comments
$\frac{D_p}{D_0} = \epsilon^2$	Buckingham ^[6]	
$\frac{D_p}{D_0} = 0.66\epsilon$	Penman ^[7]	
$\frac{D_p}{D_0} = \alpha\epsilon^\beta$	Currie ^[5]	α, β refer to pore shape, diameter, continuity, and tortuosity.
$\frac{D_p}{D_0} = \frac{\epsilon^2}{\phi^{2/3}}$	Millington & Quirk ^[8] and Jin & Jury ^[9]	Good for different textures of repacked soil sample
$\frac{D_p}{D_0} = \phi^2 \left(\frac{\epsilon}{\phi} \right)^{2+3/b}$	Campbell ^[10]	b is the Campbell pore-size distribution parameter
$\frac{D_p}{D_0} = (2\epsilon_{100}^3 + 0.04\epsilon_{100}) \left(\frac{\epsilon}{\epsilon_{100}} \right)^{2+3/b}$	Moldrup et al., ^[11] Clapp & Hornberger, ^[12] and Olesen et al. ^[13]	b can be described by following equation: $b = 13.6 \times (\text{clay fraction}) + 3.5$
$\frac{D_p}{D_0} = \epsilon^{1.5} \left(\frac{\epsilon}{\phi} \right)$	Moldrup et al. ^[11]	It is good for sieved and repacked soil sample.

Note: ϵ = the soil air content ($\text{m}^3 \text{ m}^{-3}$); ϕ = the total porosity ($\text{m}^3 \text{ m}^{-3}$).

Fig. 2 Comparison of relative soil gas diffusion coefficient by different models. The total porosity is $0.4 \text{ (m}^3 \text{ m}^{-3}\text{)}$, b (pore size distribution parameter) is 5.54, and ϵ_{100} is $0.1 \text{ (m}^3 \text{ m}^{-3}\text{)}$.

Abstract

Digital soil mapping is the creation of a spatial soil information system using field and laboratory observation methods coupled with quantitative spatial prediction techniques. Digital soil mapping follows the advancement in soil and environmental observations using proximal and remote sensing. It also utilizes contemporary mathematical and statistical techniques that allow better prediction of soil properties in areas with little or no information as well as indicating the uncertainty of such predictions.

INTRODUCTION

Digital soil mapping is defined as the creation and the population of geographically referenced soil databases generated at a given spatial resolution using field and laboratory observation methods coupled with environmental data through quantitative relationships.^[1,2] Associated with this definition, three components can be specified: the input (soil data), the process (soil inference system), and the output (spatial information system) (see Fig. 1).

Input Data

The input data required to produce digital soil maps are geo-referenced soil observations coupled with environmental variables. Soil and environmental observations can be captured using proximal and remote sensors that can cover variation over large spatial extent. Although proximal and remote sensors do not provide accurate soil details as field surveys and laboratory analysis, they allow for mapping larger extents at higher temporal frequencies (Fig. 2).

Soil Inference Systems

The soil inference systems refer to the quantitative prediction or inference of the soil attributes. This can be spatial inference system to predict soil attributes based on environmental variables, usually using spatial interpolation techniques under the constraints of the environmental

data. Non-spatial inference systems predict functional soil properties from basic soil properties, usually using pedo-transfer functions.

Spatial Information System

The soil information system is formed by the digital soil maps and soil data, where the maps are stored together with field and laboratory observations of soil properties. This includes spatial coordinates of the soil observations and also raster information of the predicted soil maps and environmental data. This information system is the first necessary component for dynamically producing geographically referenced databases created at a given spatial resolution.

Fig. 1 summarizes the process of digital soil mapping, where geo-referenced soil observations coupled with environmental variables form the input data. Under a spatial soil inference system, soil properties over the whole area can be predicted and mapped using spatial soil prediction functions (such as regression, kriging, or a combination of both, see pedometrics). This prediction is based on correlations among the environmental variables and soil attributes as well as the spatial autocorrelation of the attributes themselves. These spatially inferred soil properties can be used to predict more difficult-to-measure functional soil properties, such as field capacity, available water capacity, using pedotransfer functions under soil inference systems. All of the predicted soil properties can be used to evaluate soil functions (soil biomass production, buffering capacities, potential evaporation, etc).

Fig. 1 A general model for digital soil mapping.

Thus, digital soil mapping refers to the production of soil maps digitally ab initio, based on soil observations combined with environmental data through quantitative statistical relationships. In that sense, digital soil mapping is not simply digitizing the existing soil maps and more than just producing paper maps. There are other terminologies such as “predictive soil mapping,”^[3] which refers to the production of digital soil maps, and “environmental correlation,”^[4] which is an aspect of the spatial soil inference systems. The topic of digital soil mapping is extensively reviewed by McBratney et al. and Lagacherie et al.^[1,2]

RATIONALE

The creation of soil maps digitally started in the 1980s, when its emergence corresponded with the development

of geographical information systems (GIS) and associated data, especially digital elevation models. Digital soil mapping serves as an answer to the global needs of soil spatial information for environmental modeling. The demand is to provide soil information with reasonable accuracy, in a reasonable time, and usually with limited resources. Available soil information is neither exhaustive nor precise enough for such a system. This is because conventional soil survey and mapping techniques are slow and expensive.

Digital soil mapping has moved from the research phase^[5] to production of maps for regions, catchments, whole countries, and continent.^[6,7] Digital soil mapping is recognized as a body of science with the first review on this subject.^[1] In the review, 70% of studies have successfully mapped soil properties: including physical properties (particle size distribution and available water capacity) and chemical constituents (salt content, carbon content, and storage, nitrogen content, cation exchange capacity, etc.). Thirty percentage of the studies mapped soil classes, such as drainage, type of parent material, and soil units. Soil attributes have been found to have a good relationship with to landform and environmental variables such as geology, climate, and land cover.^[1,8] The soil properties also exhibit strong spatial dependence or trend, and with sufficient field samples can be mapped successfully by a variety of techniques.

A MODEL FOR DIGITAL SOIL MAPPING

A prediction model for spatial inference for digital soil mapping is proposed by McBratney et al.^[1] as the *scorpan* model, which can be written as:

$$S = f(s, c, o, r, p, a, n)$$
 (1)

Fig. 2 A comparison of direct measurement, proximal and remote sensors for obtaining soil information.

where S is either soil classes or soil attributes. This formulation is not for explanation but for empirical quantitative descriptions of relationships between soil and other spatially referenced factors with a view to using these as soil spatial prediction functions. The seven factors are:

1. s : soil, other properties of the soil at a point;
2. c : climate, climatic properties of the environment at a point;
3. o : organisms, vegetation or fauna or human activity;
4. r : topography, landscape attributes;
5. p : parent material, lithology;
6. a : age, the time factor; and
7. n : space, spatial position.

These environmental or the so-called *scorpan* factors can be derived from various sources (digital elevation models, remote sensing images, available soil maps, etc.), available in digital form and cover the whole area of interest. They are used to generate soil information in the form of a database where the information consists of predictions that are statistically optimal.

The general spatial soil prediction model for digital soil mapping can be written as:

$$S = f(Q) + e \quad (2)$$

where Q is the predictor variables (or *scorpan* factors) and e is an error term. The general approach is to take m number of observations S in the field at known locations and fit a

function f with a set of pedologically meaningful predictor variables Q , which will be generally raster data layers of size M in a GIS. Once the model is fitted at the m observation points, the prediction can be extended to the M points or cells in the raster, thereby giving a digital map. The efficiency of the method relies on the fact that m is much smaller than M , because S is much more difficult and expensive to measure than the Q .

The main use of the *scorpan*-spatial soil prediction functions approach is to replace the polygon-based soil maps of the past with digital maps of soil properties and classes and their associated uncertainties for areas previously mapped, or for new areas. These maps will be stored and manipulated in digital form in a GIS creating the possibility of vast arrays of data for analysis and interpretation.

EXAMPLE

The following example shows the production of a digital soil class map in Western France (around La Rochelle).^[9] The soil information system is composed of (Fig. 3):

1. Soil point observations: 4984 geo-referenced soil observations, all described by horizons and each horizon being described by depth, texture class, and Munsell color, carbonate content, salt content, gravel and stone (amount and size), organic matter content,

Fig. 3 Soil information system of La Rochelle surroundings area (France).

Fig. 4 Digital soil map of the La Rochelle area.

degree of hydromorphism, and lithology of underlying material. The database came from the available soil observations (also called “legacy data”).

2. Environmental (*scorpan*) variables represented as raster with a resolution of $25\text{ m} \times 25\text{ m}$ covering the whole area. The variables include digital elevation model and its derivatives (slope, curvatures, and compound topographical index) and soil surface cover from satellite images.

The spatial soil inference system was produced as follows:

1. Transformation of the soil observations into numerical soil classes. Soil variables are first coded into quantitative variables. First, 18 centroidal (or modal) soil profiles (one for each of the soil classes) are selected for the whole area. Then, taxonomic distances between the representative soil horizons and the observed soil horizons are calculated, and these distances are then aggregated for each profile.
2. Spatial interpolation of the numerical soil classes using regression kriging from the environmental soil factors (Fig. 3).

For each soil class, the distances between each observation i and soil class k (D_{ik}) are first modeled using a multiple linear regression with environmental factors Q as predictors:

$$D_{ik} = \alpha_{0k} + \sum_{j=1}^J \alpha_{jk} Q_{ij} + \epsilon_{ik} \quad (3)$$

The spatially correlated residuals (ϵ_{it}) of the regression are then predicted using kriging. The map of the regression prediction ($\hat{D}$) and the residuals (ϵ) is then summed to obtain the 18 soil class distance maps. For each pixel, the soil class is represented as the class with the smallest distance because the pixel is the most similar to that soil class.

The final soil map (Fig. 4) can be used for environmental modeling, and the uncertainties produced from digital soil mapping can be considered as a representation of the uncertainty or the soil mappers’ confidence.

CONCLUSION

Digital soil mapping uses a range of technologies allowing for more accurate and efficient prediction of

soil properties through optimal sampling strategies, rapid analysis of soil properties, and rapid acquisition of environmental variables over large extent. Combined with pedometric techniques, it can provide the best prediction of soil properties at the required resolution with associated uncertainties. Digital soil mapping can be thought of as a means for modernizing and systematizing traditional soil survey. A global consortium has been formed to generate a global soil map with a resolution of $90\text{ m} \times 90\text{ m}$ using this new technology (see www.globalsoilmap.net).

Drainage: Aeration and Trafficability

Norman R. Fausey

Soil Drainage Research Unit, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Columbus, Ohio, U.S.A.

Abstract

Soil drainage is a natural process by which water moves through and out of the soil as a result of the force of gravity. This natural process provides water that supports seeps, springs, stream base flow, and aquifer recharge. As water leaves the soil, air moves into the space previously occupied by the water. This process is called aeration. Soil aeration is vital for plant roots and for many beneficial organisms that live in the soil and require oxygen for respiration. As the proportion of water and air in the soil changes as a result of drainage, the ability of the soil to provide support and traction for animals and vehicles (trafficability) is altered, because the strength of the soil changes with water content. The natural drainage of the soil can be accelerated by the use of surface and subsurface drainage practices. Surface drainage diverts excess water from the soil surface directly to streams, thereby reducing the amount of water that will move into and possibly through the soil. Subsurface drainage, provided by ditches and drain pipes, collects and diverts water from within the soil directly to streams.

DRAINAGE (ACCELERATED DRAINAGE)

A complete modern reference for drainage is provided by the American Society of Agronomy.^[1] This monograph provides a comprehensive treatment of the need for, and consequences of, drainage as well as the methods and materials used for drainage, and the design of drainage systems.

Soil comprises 50–70% solid material. The solid phase of the soil is predominately mineral particles in varying proportions of sand, silt, and clay sizes. A small amount of the solid phase is organic material, and this amount decreases with depth. While the amount of the soil organic matter is quite small on a weight basis, its impact on drainage, aeration, and trafficability is substantial.^[2] This leaves 30–50% of the soil volume that comprises void space that can be filled with either air or water. The relative amounts of air and water that are present in the soil determine the ability of the soil to bear the weight of machines and animals, to provide traction, to sustain the biological life in the soil, and to maintain productive and healthy plants. Drainage plays an important role in managing the relative amounts of air and water that are present in the soil.

FACTORS THAT AFFECT SOIL–AIR–WATER RELATIONSHIPS

Bulk Density

The greater the proportion of mineral particles to void spaces, the higher the bulk density. Rocks, boulders,

stones, sand grains, silt particles, and even clay particles typically have a specific weight (density), compared to water, in the range of 2.6–2.7 Mg/m³, because they are all made up of mineral particles. If you were to pour dry soil into a bucket, with the individual soil particles having a specific density of 2.65 Mg/m³, the overall or bulk density of the soil in the bucket would typically be about 1.4 Mg/m³, because there are void spaces between the soil particles. The bulk density of the soil varies depending on the parent material from which it formed, the organic matter content, the depth below the soil surface, and the soil management. Certain processes and activities can decrease the bulk density and thereby create more void space in the soil, while other processes and activities can increase the bulk density and cause loss of void space. The growth of ice crystals in the soil during freezing can result in soil heaving and a decrease in bulk density. Cultivation loosens soil, resulting in more voids and a lower bulk density. Heavy machine traffic compacts the soil, resulting in fewer voids and a higher bulk density.

Soil Texture

Soil texture refers to the relative amounts of sand, silt, and clay size mineral particles in the soil. Sand particles are the largest, ranging from 0.05 to 2.0 mm equivalent diameter; silt particles are smaller, ranging from 0.002 to 0.05 mm equivalent diameter; and clay particles are smallest, less than 0.002 mm equivalent diameter. Equivalent diameter is used to characterize the size, because soil particles are not spherical, but rough and

random in shape. The clay size mineral particles have unique and important characteristics including an electrical charge and tremendous surface area per unit volume. Most of the electrical charges on clay size particles are negative, causing the particles to repel each other like similar magnetic poles and establishing void spaces between the particles. When considering the sand and silt particles, a useful illustration is to consider how many basketballs (representing sand particles) can fit into a bathtub. Between the basketballs, there are large void spaces. Then, consider how many marbles (silt particles) would fit into the same bathtub. The void spaces between the marbles are smaller, but the total volume of the void space is similar in both cases. By putting small particles into the large voids between the large particles, it is possible to end up with more solids and less voids. This happens in soils where the small silt and smaller clay size particles fill the spaces between the large sand size particles. Even when smaller particles occupy the spaces between larger particles, some void space will remain—usually 30–40% of the total space will remain unfilled. However, all the void spaces will be small.

Sandy soils tend to have uniformly distributed large void spaces, resulting in rapid movement of fluids through the soil. Silty soils tend to have uniformly distributed small void spaces and slow movement of fluids. Clay soils tend to have only very small void spaces and very slow movement of fluids.

Soil Structure

Mixtures of the sand, silt, and clay size particles, and the organic matter in the soil become bonded together—a result of the electrical charges on the clays and sticky organic materials in the soil—forming larger units that have a visible structure and are referred to as aggregates. Because they are large units, these aggregates can be thought of again as larger size spheres having larger voids between them. Within the aggregates, there are small voids; between the aggregates, the voids are larger. Aggregates are dynamic rather than permanent arrangements of particles. Accelerated drainage tends to reduce the general size of aggregates, but it increases their stability. Any soil tillage activities tend to disrupt aggregates, leading to smaller voids. Water moves more rapidly through soils with durable aggregates or structural units, and these soils will also typically retain more water that can be utilized by crop plants.

Pore Size Distribution

The interconnected void spaces in soil are typically referred to as pores. Most of these pores are small and can be visualized as capillary tubes, while some pores are as large as drinking straws. Pores are not usually straight and

uniform in diameter, however, being more tortuous as they twist and turn around particles and through or between aggregates. The flow and retention of fluids (air and water) in pores is ultimately what controls the drainage, aeration, and trafficability of the soil. Fluids move more easily through larger pores than through small and more tortuous pores. Burrowing insects or earthworms usually create the largest pores, called macropores. Well-aggregated soils and sandy soils also have large, well-connected pores that transmit air and water easily. Silt and clay soils with many small pores experience slow movement of fluids and entrapment of air within pores during rewetting events. Soils with a range of pores sizes, some macropores, some large pores between aggregates, and some smaller pores within aggregates are usually better suited for agricultural use and respond economically to accelerated drainage installation.

AERATION

Aerobic respiration of plant root cells and microorganisms in the soil is dependent on an adequate supply of oxygen. This oxygen is supplied to a great extent by air moving into the soil through the soil pores. When it rains, some of the rainwater enters the soil through the soil pores and displaces the air from the pores. If enough rainwater enters the soil, all the pores become filled with water and the soil becomes saturated. In the saturated pores, air movement is blocked, and the oxygen needed for respiration, by plant roots and microorganisms, cannot be supplied through the soil pores.

Under natural drainage conditions, some of the water that saturates the soil may slowly percolate downward through the soil to great depths or may leave the soil by evaporation. In some soils, the natural drainage of water occurs rapidly enough to prevent the death of plant roots and microorganisms from the lack of oxygen. In other soils, accelerated drainage is needed to provide a means to get the water out of the pores (and get oxygen in) quickly enough, so that the plant roots and microorganisms can survive.

TRAFFICABILITY

The ability of the soil to support the weight of machines and animals and provide traction for moving about on the soil is called trafficability. Trafficability depends on both bearing strength and slippage. The surfaces of soil particles are typically not smooth, and friction develops between soil particles when force or weight is applied, such as when a machine drives across the surface. Organic matter also increases the resistance of the soil to deformation and increases elasticity.^[2] It is this friction that gives the soil (bearing) strength to support the weight of the machine and (shear) strength to move the machine

forward as the wheels turn. Water acts as a lubricant between soil particles, reducing the friction and allowing the soil particles to move past one another when force or weight is applied. This results in a loss of strength and poor trafficability. With the loss of strength, sinkage and slippage occur in response to the weight of the machine and the rotational force on the tires. Similar sinkage and slippage occur under the feet of animals and humans. Drainage accelerates the removal of water from the soil pores between the soil particles and allows friction between soil particles to occur, so that the bearing and shear strength can support trafficability.

Trafficability can also be impeded by stickiness whereby clay particles stick to the tires of machines or the feet of animals and humans. This phenomenon occurs in very wet but not saturated soils with a high proportion of clay size particles.

CONCLUSION

Accelerated drainage, using ditches or drain pipes to collect the water that is free to be moved by gravity and to transport this water out of the soil, promotes the desired states of aeration and trafficability that are important for efficient and economical management of soil for agriculture, highways, recreation, and many other uses.

Drainage: Anaerobiosis

Robert O. Evans

Department of Biological and Agricultural Engineering, North Carolina State University, Raleigh, North Carolina, U.S.A.

Abstract

Excess water in the root zone displaces oxygen (O_2) and leads to a condition of anaerobiosis, also known as O_2 stress. O_2 stress leads to many adverse effects on plants including discoloration of leaves (chlorosis), accumulation of toxic substances in the root zone, yield loss, and, in extreme cases, plant death. Some plants can tolerate longer periods of excess soil water or waterlogging than others. The mechanisms of tolerance are varied and may include the ability to respire anaerobically, slowed growth or self-imposed dormancy, the development of adventitious roots, and the development of aerenchyma cells. Drainage can, as it has for centuries, be used to remove excess water from land and reduce the occurrence of waterlogging and subsequent anaerobiosis.

INTRODUCTION

Agricultural crops are obligate aerobes. As such, most plant metabolic processes require oxygen (O_2); in particular, aerobic respiration provides energy from the degradation of glucose (derived from sugars and starches in the tissue) to pyruvic acid, which is further oxidized to carbon dioxide (CO_2) and water. Anaerobiosis implies life in the absence of O_2 . Anaerobiosis is most commonly caused by waterlogging of the root zone. Under anaerobic conditions (lack of O_2), pyruvic acid produced from glucose in the root cells of higher plants is converted to CO_2 and ethyl alcohol. Ethyl alcohol tends to accumulate within root cells and, if anaerobic conditions persist, may accumulate at concentrations that can become toxic. Anaerobiosis thus creates an environment that impairs the growth rate of most plants that require O_2 for respiration. Drainage is the practice of removing excess water from land to minimize the occurrence of waterlogging. It has been an important management practice for centuries,^[1] and the consequences of poor drainage have been studied extensively in the 21st century.^[2–8]

SOIL AERATION

Either air or water occupies the pore volume of the soil. Excess water displaces air and affects the root zone environment and subsequent plant survival, growth, and yield. Processes affected by excess soil water include soil O_2 and CO_2 exchange with the atmosphere; oxidation reduction reactions in the soil and subsequent diffusion of gaseous metabolites; nutrient availability and uptake; and accumulation of CO_2 , ethylene, and other

toxic substances (Fig. 1). These conditions can impact crop production through the processes such as suppressing seed germination, restricting root growth, death of root cells, shoot wilting, chlorosis (yellowing of leaves because of the failure of leaves to produce normal amounts of chlorophyll), and slowed growth and dry matter accumulation.

The most basic consequence of excessive soil water is restriction of the supply of O_2 to roots by displacing air in the pore space and by reducing the exchange of soil air with the atmosphere. These processes are often lumped together and referred to as soil aeration.^[10] Soil aeration status has often been reported on a percentage basis of water-free pore space. Air porosities in the range of 5–20% were reported in earlier literature to be adequate for crop growth. A minimum value of 10% was reported in an early study,^[11] although the optimum air filled porosity may range from 4% to 50%, depending on soil texture, type and age of crop, and other growing conditions.^[7]

Soil aeration can also be expressed as the O_2 content of air samples extracted from the soil.^[12] In well-aerated soil, the composition of soil air closely approximates that of the atmosphere, namely, 20% O_2 and 0.03% CO_2 . O_2 contents in the range of 8–14% have been reported to be minimum for unrestricted root respiration; however, critical values are affected by many factors including soil physical properties such as texture and structure, depth in the soil, type and growth stage of crop, soil water content (SWC), organic matter present, and, of course, temperature. Numerous studies have documented declines in O_2 content to less than 2% within 24–48 hours under waterlogged conditions (Fig. 2). The rate of decline of O_2 is closely correlated to metabolic activity of microbes and roots and to soil temperature.^[13,14]

Fig. 1 Processes causing reduction in plant growth and yields owing to excessive soil water and anaerobiosis. **Source:** From Patwardhan, Nieber, et al.^[7] and Ravelo.^[9]

The oxygen diffusion rate (ODR) is the rate of exchange of soil air with the atmosphere. At the soil surface, the composition of soil air is in equilibrium or nearly so with that of the atmosphere. The O_2 content of soil air generally declines and CO_2 content resulting from the production of CO_2 during aerobic respiration increases with soil depth. At any depth, the rate of exchange of soil air with the atmosphere decreases as SWC increases (Fig. 3). Under waterlogged conditions, the O_2 content declines to less than 1% and ODR typically approaches zero.^[12] The exchange of soil air with the atmosphere occurs by two mechanisms: convection (often referred to as mass flow) and diffusion. Early work^[16] reported that O_2 transport into the soil by mass flow (convective flow) was insignificant compared

with that by diffusion. The diffusion rate of O_2 is roughly 10,000 times less through water than through contiguous, air filled soil pores. Convective transport has been considered to be important under some conditions such as shallow depths or in soils with large pores.^[7,10] Theoretical relationships for describing airflow processes in soil have been reported.^[7,12]

ODRs required for normal plant growth have been reported for several crops. In early work, plants such as sunflowers, cotton, and snapdragons stopped growing when the ODR in the soil dropped below $3.3 \times 10^{-8} \text{ kg/m}^2/\text{sec}$.^[17] Plant functions such as photosynthesis may be suppressed when the ODR drops below $2 \times 10^{-8} \text{ kg/m}^2/\text{sec}$.^[18] A value of $6.8\text{--}5 \times 10^{-8} \text{ kg/m}^2/\text{sec}$ was found for soybean^[19] with a

Fig. 2 O_2 content of soil air as influenced by duration of waterlogging at four soil temperatures. **Source:** From Trought & Drew.^[13]

Fig. 3 Relationship between ODR and SWC. **Source:** From Bornstein, Benoit, et al.^[15]

critical value of $3.3 \times 10^{-8} \text{ kg/m}^2/\text{sec}$. The required rate of diffusion is constantly changing because of the constant changes in growing conditions.^[12]

PLANT RESPONSES TO POOR AERATION

As noted earlier, there are many crop responses to poor aeration that results from waterlogged or excessive soil water conditions. A prolonged lack of O_2 suppresses and, in many cases, prevents the germination of most seeds. While seeds of many species can tolerate short periods of limited aeration, cell division and growth rate are reduced when the supply of O_2 is cutoff, even for a few hours.^[13,20,21] Fausey and McDonald^[21] observed that emergence suppression was much greater at warmer temperatures.

Low O_2 diffusion limits root respiration and the exchange of gaseous metabolites such as CO_2 and ethylene. There is extensive evidence that the rapid decline in O_2 content is the primary mechanism of injury to roots.^[2,22–24] Although ethylene accumulation was once thought to be a direct cause of root injury,^[25] Cannell and Jackson,^[2] citing the works of others, concluded that ethanol accumulation in roots likely did little more than modestly depressing the root growth. Root injury tends to be in the form of slow or terminated growth during waterlogged conditions because of a lack of energy normally obtained through aerobic respiration. O_2 content within the root zone often drops below critical levels within hours of waterlogging.^[26] Again, growth retardation responses can be rapid, especially at higher temperatures.^[27] In studies involving static water tables, investigators have reported little or no root penetration below the water table.^[28] McDaniel^[29] observed that corn roots responded quickly to saturation, with all growth ceasing within 24 hours. He observed that three days of waterlogging significantly affected root mass, maximum root depth, and consumptive water use for the remainder of the growing season. Like roots, plant shoots can respond quickly to flooded conditions. Frequently cited symptoms of above-ground plant parts to waterlogging include shoot wilting,^[30] increased resistance to water flow,^[31–35] elevated plant temperature,^[36] and chlorosis that leads to slowed growth and dry matter accumulation.^[12,23,24,31,36–38]

In soils with a high water table (water table less than 2m from the soil surface during the growing season), yield of most crops can be related to the water table depth. The yield response is generally not a direct response to the position of the water table but rather to the indirect effects the water table has on aeration status, nutrient availability, and soil moisture that is available to the plant. At very shallow water table positions, most soil pores are filled with water and the crop experiences aeration or O_2 stress (anaerobiosis), which in turn suppresses yield. A common method for quantifying the stress imposed on a crop by excess soil water or lack of

Fig. 4 Relationship between crop yield and flooding duration. Source: From Howell & Hiler^[39] and Hiler.^[40]

O_2 relies on experimental determination of crop yield, in response to an elevated water table. The most frequently applied approach has been to grow crops in lysimeters and examine the effect of inundation or waterlogging on the crop yield. This approach does not directly account for the stress caused by lack of O_2 , excess CO_2 , or accumulation of toxins within the soil profile; but it does provide one method of relating crop yield to a condition of obvious stress.^[7]

Several general conclusions can be developed from inundation studies. Crop-yield reductions increase as the flooding duration increases, as shown in Fig. 4. This conclusion is consistently supported by most studies for most crops. Many crops can tolerate short-term periods of waterlogging, but the tolerance duration depends on many factors. One important factor affecting crop-yield response to excess water and poor aeration is the crop's stage of development. Most crops studied tend to be more susceptible during earlier stages of development (preflowering).^[26,41–43] Another important factor is the accumulation of toxic substances found in the soil associated with anaerobic respiration. Nitrite is the first potentially toxic product of anaerobic respiration. At low pH, incomplete conversion of nitrate to N_2 gas can favor the formation of nitrous acid.^[44] Under extended reducing conditions where E_h values drop below 100 mV, iron and manganese can be reduced and accumulate at toxic concentrations. If anaerobic conditions persist, hydrogen sulfide can be produced that is reported to kill roots at concentrations greater than 2.5 ppm.^[45]

DRAINAGE TO REDUCE ANAEROBIOSIS

A primary goal of agricultural drainage in humid regions is to lower the water content of the root zone to provide adequate aeration following excessive rainfall or irrigation such that it leaves a soil condition that is favorable for crop growth.^[46] Several techniques are available that improve drainage and reduce excess water-related stress. Surface drainage^[47] can be achieved by a system of open ditches,

typically installed on 100–200 m intervals parallel to each other in the general direction of the prevailing slope. To encourage surface runoff and reduce surface ponding, fields are often graded and sometimes crowned into a turtleback shape. Field ditches are typically 0.5–1.5 m deep and discharge into collector canals typically laid out on 1 or 2 km grids. Irregularly spaced ditches are often used to drain depressional areas. Bedded rows parallel to the field ditches are sometimes used to elevate the seedbed and help reduce water stress while the plants are small. Surface drainage systems encourage aeration of the root zone by quickly removing surface water. Once surface ponding is eliminated, the water table declines rapidly during periods with moderate to high potential evapotranspiration, which is usually the case during the growing season. Thus, a surface drainage system encourages reaeration of the root zone by reducing the volume of water entering the soil profile, while the water table is actually lowered by some means other than direct drainage, i.e., evapotranspiration. As the water table declines, air replaces the water that is removed.

Excess water can also be removed by a system of subsurface drains^[48–50] comprising clay tile, perforated plastic tubing, or unlined mole drains. In general, 100–150 mm diameter tile or tubing is buried 1–1.5 m deep at intervals of 10–50 m. The subsurface drainage pipes generally flow into to an open ditch or stream. In United States, subsurface drainage systems have typically been designed to remove 125 mm (0.5 in.) of water per day, for grain crops. Higher design rates up to 250 mm/day have been used for vegetable crops grown in organic soils. Subsurface drainage systems directly improve root zone aeration by lowering the water table following heavy rainfall. In many cases, crop protection is also provided as a result of the water table being lowered before the rainfall. In this case, subsurface drainage provides adequate soil storage to prevent the water table from rising into the root zone and as a result aerobic conditions may persist throughout the rainfall/drainage event. As a general rule, aeration and O₂ diffusion into the root zone are associated with increased water table depth and greater drained porosity.^[51,52] No degree of site drainage will provide the “optimal” soil water environment in all situations. Drainage requirements depend on many inter-related factors including rainfall duration and intensity, soil physical properties, soil and air temperature, type of crop being grown, and the growth stage of the crop.

CONCLUSION

Excess water in the root zone displaces O₂ and leads to a condition of anaerobiosis, also known as O₂ stress. O₂ stress leads to many adverse effects on plants including discoloration of leaves (chlorosis), accumulation of

toxic substances in the root zone, yield loss, and, in extreme cases, plant death. Some plants can tolerate longer periods of excess soil water or waterlogging than others. The mechanisms of tolerance are varied and may include the ability to respire anaerobically, slowed growth or self-imposed dormancy, the development of adventitious roots, and the development of aerenchyma cells. Work using molecular genetics techniques has shown that specific genes are responsible for flooding tolerance^[53] and provides future promise as a means of improving the flooding tolerance of major agronomic crops. Drainage can, as it has for centuries, be used to remove excess water from land and reduce the occurrence of waterlogging and subsequent anaerobiosis. Improved knowledge of the physiological mechanisms of plant tolerance may lead to alternatives for overcoming the effects of poor soil aeration.^[2] However, drainage continues to be the most viable alternative for reducing the frequency and duration of anaerobiosis resulting from excess soil water.

Drainage: Water Quality

James L. Baker

Department of Agricultural and Biosystems Engineering, Iowa State University, Ames, Iowa, U.S.A.

Abstract

Artificial subsurface drainage is required on many agricultural lands to remove excess precipitation and/or irrigation water in order to provide a suitable soil environment for plant growth and a soil surface capable of physically supporting necessary traffic, e.g., for tillage, planting, and harvesting. Although this drainage makes otherwise wet soils very productive, subsurface drainage alters the time and route by which excess water reaches surface waters and can carry nutrients, pesticides, bacteria, and suspended solids to surface waters and cause non-point source pollution problems. The net water quality impact of subsurface drainage considered here is determined by a comparison to the same cropping system not having subsurface drainage (not on the fact that the existence of adequate drainage will affect land use). The degree of pollutant transport with surface runoff and subsurface drainage is determined by the product of the volumes of water and the pollutant concentrations in the water. These are both influenced by environmental conditions, pollutant properties, and management factors, and their interactions with subsurface drainage are discussed.

ENVIRONMENTAL CONDITIONS

Soils/Hydrology

Whether water added to the soil surface as precipitation or irrigation infiltrates or becomes surface runoff is critical to water quality. Topography/slope, soil moisture content, texture, and soil structure, including the existence of preferential flow paths or “macropores,” can affect both the rate and route of water infiltration (as shown in Fig. 1). While different drain spacings are used to provide a desired “drainage coefficient” (e.g., 0.5 in./day) based on the internal drainage characteristics of the subsoils, the conditions of the surface soil will determine what percentage of applied water (rain or irrigation) will infiltrate. In general, the existence of subsurface drainage increases the volume of infiltration and thus decreases the volume of surface runoff (and pollutant loss with that runoff), increases shallow percolation, and lowers water tables. This effect will be more pronounced for “lighter” soils that have higher infiltration rates and lower water holding capacities. These changes affect the final quality of cropland drainage because of differences in time and type of soil–water–chemical interactions. Surface runoff allows water to come in contact only with the surface soil and materials such as crop residue and surface-applied fertilizers, manures, and pesticides present on it for short periods of time. On the other hand, water that infiltrates and percolates through the soil comes in intimate contact with all the soils in the profile to at least the depth of the

tile drain, and generally, for much longer periods of time. The soil residence time is shorter for that portion of infiltrated water intercepted by the tile drains than for water that must flow through the underground strata to appear as base flow.

Climate/Precipitation

The timing, amount, and intensity of water inputs, including precipitation and irrigation, relative to evapotranspiration (ET) determine the timing and amount of excess water that will leave agricultural land as surface runoff and subsurface drainage. Inputs at low intensities generally will totally infiltrate, but as intensities increase past the rate of infiltration, surface runoff begins. As just discussed, decreased antecedent soil moisture contents (resulting from the existence of artificial subsurface drainage) increase infiltration rates, and the volume of surface runoff generally is decreased when subsurface drainage exists. This effect will be more pronounced for areas where input intensities often exceed the rates of infiltration.

For a given crop and climatic region, the amount of ET is relatively constant, so the volume of subsurface drainage is very much dependent on the amount of input water above that value. As an example, in a 4-year Iowa tile drainage experiment,^[1] during a low rainfall year, only a trace of subsurface flow occurred; in a wet year (116 cm of precipitation vs. the average of 80 cm), there was 29 cm of flow; and the overall average flow for the 4 years was 15 cm.

Fig. 1 Schematic of transport processes.

POLLUTANT PROPERTIES

Persistence

Pollutants that have a limited existence in agricultural lands because of plant uptake/chemical transformation (i.e., nutrients), degradation (i.e., pesticides), and die-off (i.e., microorganisms) have different potentials for off-site transport with water based on their persistence. Because surface runoff is much more of an immediate process than subsurface drainage, concentrations of non-persistent pollutants in subsurface drainage are usually lower than in surface runoff. This effect will be more pronounced, the lesser the persistence is. However, the “route” of infiltration, where in some cases the drainage water moves quickly through the soil profile because of macropores (see Fig. 1), plays a role and can somewhat negate the expected dissipation effect.

Adsorption/Filtration

Based on their chemical properties and/or their physical size, some pollutants transported down into and through the soil with subsurface drainage are removed from the flow stream by the soil. In particular, pollutants that are positively charged [e.g., ammonium–nitrogen ($\text{NH}_4\text{-N}$)] and larger, less soluble, organic compounds (e.g., some pesticides) can be attenuated by adsorption to soil clay and organic matter. Inorganic P ions can be removed by complexation or precipitation with soil cations. Microorganisms and sediment can be filtered out by small soil pores. Thus, in general, with the exception of soluble salts of nitrate–nitrogen ($\text{NO}_3\text{-N}$), sulfate, and chloride anions, pollutant concentrations in subsurface drainage are lower than in surface runoff. This effect will be more pronounced, the greater the interaction between the pollutant and soil is.^[2]

For sediment itself, because soil erosion is dependent on the erosive ability and transport capacity of surface runoff, reducing the runoff flow rate and volume with subsurface drainage reduces sediment loss. For example, in a 6-year

study in the lower Mississippi Valley, surface runoff volumes from plots on a clay loam soil with subsurface drainage were 34% less than for plots without subsurface drainage, and the corresponding soil loss of 3500 kg/ha/yr represented a decrease of 30%. For the plots with subsurface drainage, both sediment concentrations and losses in subsurface drainage were about one-tenth of those in surface runoff.^[3]

For nitrogen (N), loss from poorly drained soils is usually much less than that from soils with improved drainage systems.^[4] While significant N can be transported with sediment (often sediment has at least 1000 ppm N), land needing subsurface drainage is usually not highly susceptible to erosion, and N loss is dominated by soluble inorganic N loss. In a three-year tile-drained watershed study in northeast Iowa,^[5] $\text{NO}_3\text{-N}$ losses in solution represented over 85% of the total N losses, including $\text{NH}_4\text{-N}$, organic N in solution, and N associated with sediment. In a five-year study in East Central Iowa,^[6,7] where nutrient concentrations in both surface runoff and subsurface drainage from cropland were monitored, $\text{NO}_3\text{-N}$ concentrations in subsurface drainage averaged about 12 mg/L and 2–3 times those in surface runoff. While $\text{NH}_4\text{-N}$ concentrations were usually 2–10 times higher in surface runoff, on an absolute scale, the concentrations were overall much lower than those for $\text{NO}_3\text{-N}$ and constituted only a fraction of the total N loss.

For phosphorus (P), transport is primarily in surface runoff with sediment (often sediment has at least 500 ppm P) and dissolved in surface runoff. For conventionally tilled cropland, about 75–90% of P transported in surface runoff is with sediment. In areas where soil erosion is minimal, soluble P in surface runoff water can dominate transport. The soluble P in surface runoff (and subsurface drainage) is regulated by adsorption/desorption characteristics of soil. Therefore, with P in surface soils generally much higher than in subsoils, subsurface drainage usually has much lower soluble P concentrations than in surface runoff.

For pesticides, because of their adsorption characteristics, like with P, concentrations in surface runoff water are usually much greater than in subsurface drainage. However, this effect is even more dramatic for pesticides because unlike P, pesticides have a limited persistence, which decreases their potential for movement with subsurface flows with long travel times. In a series of studies on herbicides in surface and subsurface drainage,^[8–10] atrazine concentrations in May (the period of application) were 75 $\mu\text{g/L}$ in surface runoff for plots with surface drainage only and were 51 $\mu\text{g/L}$ and 1 $\mu\text{g/L}$ in surface runoff and subsurface drainage, respectively, for plots that also had subsurface drainage. Not only were there much lower atrazine concentrations in subsurface drainage water but the presence of the subsurface drains delayed and reduced surface runoff such that concentrations in surface runoff from the plots with subsurface drainage were reduced about one-third.

For bacteria, a review by Crane et al.^[11] showed that fecal coliform counts in surface runoff from manured lands often were greater than 10,000/100 ml. In a comparison of surface runoff and subsurface drainage, Culley and Phillips^[12] found similar counts (>10,000/100 ml) for fecal coliform in surface runoff from both manured and fertilized plots, but with much lower counts (<5/100 ml) in subsurface drainage.

MANAGEMENT PRACTICES

Tillage Systems

The hydrologic interactions between tillage systems and subsurface drainage that affects water quality involve how tillage affects the timing, route, and volume of infiltration (and hence the relative volumes of subsurface drainage and surface runoff). In a review of the hydrologic effects of conservation tillage, Baker^[13] noted that changing the relative volumes of subsurface drainage and surface runoff can also affect chemical concentrations in those carriers. In general, increasing infiltration increases the time for beginning of surface runoff, which in turn reduces the concentrations of chemicals at the soil surface (shown as a thin mixing zone in Fig. 1) and therefore in surface runoff. However, the effect of conservation tillage on infiltration is time dependent. For the first storm after any tillage there is usually less runoff from the tilled soil, although on an annual basis, conservation (or less) tillage often results in lower total surface runoff volumes.

Cropping

As with tillage, the hydrologic interactions between cropping systems and subsurface drainage that affects water quality involve how cropping affects the timing, route, and volume of infiltration (and hence the relative volumes of subsurface drainage and surface runoff). A major difference between perennial crops such as forages, and row crops such as corn and soybeans, is the volume and timing of ET demands. In general, with higher, more consistent ET, perennial crops would have lower total drainage volumes. A bigger effect of cropping would be the effect of needed chemical applications and their potential losses. For example, the large amounts of N needed (added, recycled, and/or fixed) in a continuous corn or corn-soybean rotation mean there are usually high NO₃-N concentrations in the soil profile, and hence in subsurface drainage when it occurs. However, for grasses and alfalfa, NO₃-N concentrations in subsurface drainage are much lower.^[14,15]

Controlled Drainage

In areas where subsurface drainage exists, controlling the timing of outflows has been suggested as one method to

reduce chemical losses. This controlled drainage could reduce losses by reducing both subsurface volumes and chemical concentrations. The potential for reduced concentrations is probably the greatest for NO₃-N, where the process of denitrification would reduce NO₃ to N gases in the soil profile where high water tables and the presence of organic matter drives the system anaerobic. The results summarized from 125 site years of data from North Carolina^[16] showed that controlled drainage reduced subsurface drainage volumes on an average of 30% compared to uncontrolled drainage systems. Reductions in N and P lost with subsurface drainage were 45% and 35%, respectively. While almost all the reduction of P loss was due to decrease in drainage volume; for N, reductions in NO₃-N concentrations also contributed to the reduction.

CONCLUSION

The total effect of surface drainage on surface water resources receiving drainage from agricultural lands involves the relative volumes of surface runoff and subsurface drainage and the relative concentrations of sediment, nutrients, pesticides, and bacteria. In general, the existence of subsurface drainage increases infiltration rates, which delays and reduces the volume of surface runoff. For pollutants lost mostly with surface runoff, which include sediment, NH₄-N, P, pesticides, and bacteria, not only is the volume of the carrier reduced but also the concentrations. This is because delayed runoff and more water moving through the surface-mixing zone reduce the amounts of contaminants at the soil surface available to interact with added water and overland flow. Thus the only real water quality negative to subsurface drainage is the increased volume of water moving thorough the soil profile carrying the soluble unadsorbed NO₃-N anion. The use of improved in-field N management in the way of rate, method, and timing of N applications has some potential to reduce this problem.^[17] However, other practices such as controlled drainage or construction/reconstruction of wetlands may be needed to provide some NO₃-N reduction treatment. Alternatively, reducing the amount of row crops grown on subsurface-drained lands could have a large impact although the economics of doing that would be quite negative.

Drought: Drought Resistance

Graeme C. Wright

Nageswararao C. Rachaputi

Queensland Department of Primary Industries, Kingaroy, Queensland, Australia

Abstract

This entry concentrates on crop production, and in that context drought is a term used to define circumstances in which growth or yield of the crop is reduced because of insufficient water supply to meet the crop's water demand. During the 1960s to 1980s, most of the drought research was dedicated to understanding the mechanisms of survival and growth under drought conditions. It is only after that attention has been given to recognizing the complex nature of drought and to separating the productivity of crop plants under drought from survival mechanisms. Drought resistance in modern agriculture requires sustainable and economically viable crop production, despite stress. However, plant survival can be a critical factor in subsistence agriculture, where the ability of a crop to survive drought and produce some yield is of critical importance.

INTRODUCTION

Drought can be considered as a set of climate pressures that can result from a combination of heat, aerial, or soil water deficits as well as salinity. The diversity of drought created from these phenomena has led to the selection of numerous types of resistance mechanisms that operate at different levels of life organization (molecule, cell, organ, plant, and crop). Decades of research have been dedicated to the understanding of these mechanisms, with a premise that the improved understanding would contribute to the long-term improvement of plant and crop production under drought conditions.^[1]

DISCUSSION

Hence, in the context of agricultural production, drought resistance in a crop can be best defined in terms of the optimization of crop yield in relation to a limiting water supply.^[2] Multitudes of options exist for farmers to alleviate the effects of drought on crop yield, depending on the probability of drought. These can be categorized into management and genetic options, although they can be integrated into a package to manage drought in the target environment. The basis of most management technologies adopted by farmers revolves around optimizing water conservation and its subsequent utilization by the crop. Examples include the use of deep tillage to increase rainfall infiltration, stubble retention to minimize soil evaporation,^[3] and intercropping.^[4] Genetic options include the use of the best locally adapted varieties or landraces as well

as relaying and intercropping varieties with varying phenology to exploit differences in timing and severity of drought patterns.^[5]

Advances in crop drought resistance and associated improvements in productivity under drought are most likely to come from genetic improvement programs that can apply the wealth of knowledge created over the 20th century. As Richards^[6] states, however, it will never be possible to *overcome* the effects of drought, any progress is likely to be slow, and the gains will only be small. The following sections will therefore concentrate on opportunities and emerging technologies for the improvement of drought resistance in crop plants, using genetic enhancement.

DROUGHT RESISTANCE TRAITS

Levitt^[7] has proposed a terminology for drought resistance and its subdivision into different categories based on different mechanisms. These three categories of drought resistance have been widely accepted, and they continue in a slightly modified form to provide a framework for evaluating potential traits for use in crop breeding programs.^[8–10] They are drought escape, dehydration postponement, and dehydration tolerance.

Drought Escape

Matching the phenology to the expected water supply in a given target environment has been an important strategy for improving productivity in water-limited environments.^[11] In most crop species, there is large genetic variability in

phenological traits, and these traits are highly heritable and amenable to selection in large-scale breeding programs.^[12] Matching phenology has proven to be a highly successful approach in environments that have a high probability of end-of-season drought stress pattern.^[13]

Dehydration Postponement

Crops use a variety of mechanisms to maintain turgor in leaves and reproductive structures, despite declining water availability. They can effectively regulate water loss from leaves via stomatal control, with large varietal differences in stomatal conductance in response to leaf water potential recorded in cereals^[14] and grain legumes.^[15]

Production of abscisic acid (ABA) has been implicated as a mechanism behind stomatal control.^[16] Other benefits of ABA, including maintenance of turgor in wheat spikelets and subsequent grain set, have also been reported.^[17] Subsequent stimulation of research activity into the use of the ABA trait in crop breeding programs has followed. However, Blum^[18] concluded that while ABA is undoubtedly involved in plant response to drought stress and even perhaps in desiccation tolerance, its value in the context of drought resistance breeding is questionable.

Osmotic adjustment (OA) has been reported as an important drought-adaptive mechanism in crop plants where solutes accumulate in response to increasing water deficits, thereby maintaining tissue turgor despite decreases in plant water potential.^[19] OA has been shown to maintain stomatal conductance, photosynthesis, and leaf expansion at low water potential,^[20] as well as reducing flower abortion^[21] and improving soil-water extraction despite declining water availability.^[22,23] More research has confirmed that OA is directly associated with grain yield (GY) in a number of crops, including wheat,^[24,25] sorghum,^[26] and chickpea.^[27]

Dehydration Tolerance

The ability of cells to continue metabolism at low-leaf water potential is known as dehydration tolerance. Membrane stability and the associated leakage of solutes from the cell^[28] provide one measure of the ability of crop/genotypes to withstand dehydration. Sinclair and Ludlow^[29] have suggested that the lethal water potential is a key measure of dehydration tolerance, with significant variation among crops and cultivars observed. Some stages of the plant's life cycle are less susceptible to large reductions in water content. For instance, prior to establishment of a large root system, seedlings may often survive large reductions in water content.^[30] Protection against lethal damage in seedlings and seeds is correlated with the accumulation of sugars and proteins.^[31] Proline has also been implicated in cellular survival of water deficits and has also been involved in OA. Its role as a selection trait for enhanced drought resistance has been questioned.^[32] Although the

work on drought resistance mechanisms has produced a few promising leads, their application in practical breeding programs has been limited.

HEIRARCHY OF DROUGHT RESISTANCE TRAITS

Richards^[6] suggests there are two major principles to consider when identifying critical traits to use in breeding programs aimed at improving productivity under drought, namely, the influence of the trait in relation to time scale and to level of organization.

Time Scale

Traits that influence drought resistance in crops can span a wide range of time scales. Short-term responses to water deficit, e.g., include many of the processes covered earlier (heat-shock proteins, stomatal closure, OA, and ABA), which Passioura^[2] suggests are often primarily concerned with "metabolic housekeeping." Although these processes are important, they tend to be associated with crop survival rather than with events that influence crop productivity. At the other end of the time scale are longer-acting processes such as control of leaf area development, which can be modulated by the crop to adjust water supply to prevailing demand.^[33] It is not always clear which processes are operating to control these balances, but presumably hormonal signals are involved. Passioura^[2] argues that researchers need to distinguish between traits linked to short-term responses that might be important for overall drought resistance and those that are unimportant when integrated over longer time scales.

Level of Organization

The capacity of the trait to influence yield is related to the level of organization (molecule–cell–organ–plant–crop) in which the trait is likely to be expressed.^[34] Richards^[6] cites an example that despite the doubling of crop yields since 1900, the rate of leaf photosynthesis, which is expressed at the cellular-organ level, has remained the same or decreased. Increases in leaf area during this period have been largely responsible for the yield increases. It is concluded that the closer the trait is to the level of organization of the crop the more influence it will have on productivity (Fig. 1).

DROUGHT RESISTANCE TRAITS IN TERMS OF THE PASSIOURA WATER MODEL

Passioura^[2,34,35] argues that there are no traits that confer global drought resistance. Also, given the earlier discussion which clearly suggests that short-term responses to drought stress operating at the cellular level may have no bearing on

Fig. 1 The hierarchy of processes leading to crop yield.

the yield of water-limited crops, crop productivity is best analyzed from the top down. Here the thinking has shifted from understanding defense mechanisms for survival to applying this knowledge to optimize economic productivity under a given water-limited condition.

Passioura proposed that when water is the major limit, GY is a function of the amount of water transpired by the crop (T), the efficiency of use of this water in biomass production (WUE), and the proportion of biomass that is partitioned into grain, or harvest index (HI), thus:

$$GY = T \times WUE \times HI \quad (1)$$

It was argued that individual traits could be assessed in terms of their contribution to each of these functional yield components and thereby increase yield under drought. The identity has provided a framework to more critically identify and evaluate important drought resistance traits. The following examples demonstrate the utility of this approach.

In a number of crops, improvement in the WUE trait has been achieved via selection for carbon isotope discrimination,^[36] or correlated surrogate measures.^[37–39] Readers are referred to several reviews for more details on this subject.^[6,40,41]

In maize, increased partitioning to the grain (or higher HI) has been brought about by using an ideotype selection index that focused on a reduction in anthesis to silking interval.^[42] GY of the final selections increased by 108 kg/ha/cycle and came about by an increase in HI, with no change in final biomass relative to the parents.

Wright et al.^[43] proposed that estimates of each of the water model components for a peanut crop could be derived from simple and low-cost measurements of total and pod biomass at harvest, from estimates of WUE from correlated measures of specific leaf area, and by reverse engineering the TDM component of the water model, such

that $T = TDM/TE$. A selection study is being conducted on four peanut populations, in which a selection index approach utilizing T, WUE, and HI is assessing the value of these traits in a large-scale breeding program in India and Australia.^[44]

CONCLUSION

Although drought is commonly referred to as “prolonged water deficit” periods during a crop’s life, it is indeed a complex syndrome with various climate pressures operating together in infinite combinations, resulting in significant reductions in crop performance. Historically, options for managing agricultural drought have revolved around management techniques such as deep tillage, mulching, intercropping, etc. However, options for drought management will increasingly be based on the genetic improvement of crops for targeted environments. With genetic options, matching phenology to water availability in target environments has proven to be highly a successful approach. Although our understanding of drought resistance mechanisms has improved significantly, it is essential to distinguish the traits linked to short term responses from those which are important when integrated over longer time scales.

Drought: Precipitation, Evapotranspiration, and Soil Moisture

Joshua B. Fisher

Konstantinos M. Andreadis

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, U.S.A.

Abstract

Drought is major hydrological disaster for human society and encompasses multiple hydrological components. There are numerous definitions of drought, many of which do not include transpiration or evaporation [evapotranspiration (ET)]. In this entry, we describe the role of ET in drought, and why ET is important to consider when assessing drought. We emphasize the dynamic roles of ET, precipitation, and soil moisture, with a focus on vegetation response during water stress. Finally, we conclude with a case study example of drought in Amazonia.

INTRODUCTION

Drought ranks as one of the most expensive natural disasters in terms of human welfare and food security. For example, in the United States, the annual cost of drought relief measures has been estimated between US\$6 billion and US\$8 billion. Droughts can cover very large areas and last for several years with the so-called megadroughts documented from medieval times.^[1] In general terms, drought is caused by extremes within the natural variability of climate but can be exacerbated by human activity (e.g., deforestation). The literature on drought is extensive, with definitions categorically ranging from meteorological (climatological, or atmospheric), agricultural, hydrologic, and socioeconomic (e.g., management based),^[2–5] but we focus here on the vegetation transpiration and evaporation [actual evapotranspiration (ET)] component of drought.^[6] From a vegetation perspective in general, physical drought is the drying of soil such that the overlying vegetation experiences physiological water stress manifested in a reduction of productivity, loss of leaves/needles, and, ultimately, mortality. As such, a given soil moisture content (SMC) would correspond to different classes of drought, depending on the ability of vegetation to adapt to decreased soil moisture. For instance, some species or stages of succession may have plants with deep roots that can tap deep sources of soil moisture, even the groundwater table, so the ability of these plants to withstand what would otherwise be considered a drought may, in fact, not be considered a drought for some time.^[7] Other species, however, may be poorly adapted to low levels of soil moisture through sparse root distribution, low water use efficiency, or high temperature sensitivity and thus may enter into a drought much more quickly than other, better adapted, species.

SMC is inherently coupled directly to precipitation (PPT) and ET, with PPT as the moisture input and ET as the moisture withdrawal; soil water-holding capacity acts as the intermediate “bucket” size if considering a bucket model of SMC change. Among these three variables (i.e., SMC, PPT, and ET), the end-members of SMC can be outlined as follows: 1) for two areas with equivalent PPT and ET, SMC may be different because of different SMC retention properties (e.g., sandy soils may hold less water than soil with more clay); 2) for two areas with equivalent soils and PPT, SMC may be different because of different ET; and 3) for two areas with equivalent soils and ET, SMC may be different because of different PPT. The same exercise can be applied for areas to have similar SMC (e.g., two areas with equivalent soils: one with high PPT and high ET and the other with low PPT and low ET). By this definition, and with reference to the title of this entry, ET can vary under drought or non-drought situations, although ET will go to zero under persistent and intense drought. Between the ET components, transpiration will go to zero as drought persists (assuming no deep water sources) because stomata is close to avoid water loss (assuming no leaky stomata),^[8] and plants will maintain respiration through carbon stores; evaporation from the soil surface will also go to zero as the soil dries out (assuming no hydraulic lift/redistribution from deep water sources).^[9] The role of ET in drought is particularly pertinent in already water-limited environments where increasing temperatures over time accelerates ET, which leads to greater drought severities.^[10]

Plants are typically able to withstand relatively short periods of SMC decline, so a given day with no PPT and high ET may not be considered a drought. Although there are different metrics of drought that take ET into account such as the widely used Palmer Drought Severity Index,^[2] which

Fig. 1 PPT (black) and CWD (gray) over 10 years for a site in Amazonia, described in Phillips et al. The light colors are the daily values, and the dark colors are the 30-day moving averages.

Source: From Phillips, Aragão, et al.^[11]

uses the potential ET, it is the *cumulative water deficit* (CWD) that plants respond to—i.e., the summation of days in which the soil water deficit (SWD) is below a critical water stress threshold. SWD may be calculated as follows:

$$\begin{aligned} \text{If } \text{PPT} - \text{ET} > 0, \text{ Then } \text{SWD}_1 &= 0, \\ \text{Else } \text{SWD}_1 &= \text{P} - \text{ET} + \text{SWD}_0 \end{aligned}$$

where the subscripts indicate adjacent time steps. The maximum CWD (MCWD) reached during the time period of interest relative to the time-averaged climatological MCWD may be considered “drought.”^[11] Both the length of the CWD and the MCWD in a given period must surpass the long-term means of the two for that period to be considered a drought although a corresponding vegetation water stress response is also necessary.

An example of MCWD drought and vegetation response is shown in the *Science* paper by Phillips et al.,^[11] *Drought sensitivity of the Amazon rainforest*. Here, we describe how the measurements of anomalously low PPT indicated the possibility of an intense drought over Amazonia—the lowest PPT at the time, in fact, in the past 100 years. With few soil moisture measurements available, SWD was constructed from measured PPT, estimated ET using meteorological measurements,^[12,13] and measurements of the soil water-holding capacity. We calculated MCWD at 136 sites where we also observed vegetation response and determined that sites experiencing the greatest hydrologic drought as defined by MCWD also had the greatest vegetation response, specifically mortality and biomass loss. It can be seen at one of the sites, e.g., Fig. 1, that PPT varies seasonally, as does CWD, but in 2005 (also 1997 and 2001)

CWD spikes well beyond the mean CWD for the 10-year record. In this analysis, the length and peak (MCWD) of the CWD spike vary by site and are proportional to the vegetation response (e.g., mortality).

CONCLUSION

Evaporation and transpiration are critical components to drought although many traditional definitions of drought ignore ET. Vegetative drought inherently implies a response from vegetation, and this response must be calculated from a CWD, as $\text{ET} > \text{PPT}$ adds up over time, drying out the soil. In the absence of soil moisture measurements, soil moisture may be calculated from PPT and ET. Even with soil moisture measurements, the understanding of the bioclimatic variables controlling ET helps elucidate and predict how drought will change given changes in the controlling factors.

Earthworms

Patrick J. Bohlen

MacArthur Agro-Ecology Research Center, Lake Placid, Florida, U.S.A.

Abstract

Earthworms are arguably the most important soil animals due to their well-recognized role in organic matter breakdown, increased nutrient turnover, and soil structural development. Assessing the role of earthworms in soil requires an understanding of the characteristics of their different ecological groups and the way in which they interact with soil characteristics, such as soil texture and organic matter content, over different scales of time and space. Earthworms can process large amounts of litter and soil in many productive ecosystems, and their activity is often associated with faster nutrient turnover rates. Their effects on nutrient cycling and organic matter turnover are mediated by their interaction with soil microorganisms. Their effects on soil structure are usually beneficial, such as improving soil aggregation, but in some cases are detrimental, such as increasing soil compaction and bulk density. The majority of studies examining the effects of earthworms on plant growth have reported that earthworms enhance plant growth. There are instances in which earthworms might be considered pests, but in general, they are considered to greatly benefit soil fertility. Agricultural practices influence earthworm populations, which generally decrease in response to increasing tillage or decreasing organic matter. Earthworms exhibit varying sensitivity to pesticides, heavy metals, and other soil pollutants and have potential for use in land reclamation and processing of organic wastes.

INTRODUCTION

Earthworms are perhaps the most important soil animals in terms of their influence on organic matter breakdown, soil structural development, and nutrient cycling, especially in productive ecosystems. Aristotle called them the “intestines of the earth” and the eminent 19th century biologist, Charles Darwin, spent many years observing their major influence on humus formation and soil transport.^[1] A vast body of scientific literature on earthworms has been published over the past several decades, which has greatly expanded our understanding of their role in ecological systems and has identified gaps in knowledge and suggested promising areas for further research. Despite this extensive literature, we lack knowledge of many aspects of earthworm biology and ecology and their long-term effects on soils and ecosystems.^[2,3]

EARTHWORM BIOLOGY AND CLASSIFICATION

Earthworms are terrestrial annelids with bilateral symmetry and corresponding external and internal segmentation. They have a thinly pigmented cuticle bearing setae on all segments except for the first two. All earthworms are hermaphroditic. Their gonads are situated in specific segments, which vary among different taxa. When sexually mature, they develop a swollen area of the epidermis called a clitellum. This region produces a cocoon in which one or more eggs are deposited, and then, the cocoon is passed

over the anterior segments and deposited in or on the soil. The young ones develop within the cocoon, and the newly hatched worms resemble the adults. The time to hatching and reproductive maturity vary widely among different earthworm species and are influenced by environmental factors.

Earthworms are classified within the phylum Annelida and the class Oligochaeta, which consists of as many as 36 families worldwide. About two-thirds of Oligochaete families comprise aquatic or semiaquatic worms, and the remaining families comprise mostly or exclusively terrestrial worms or earthworms. There are over 3500 known earthworm species, and it is estimated that the global total may be twice that number. Distinct taxonomic groups have arisen on every continent except Antarctica, and some groups are distributed throughout the world.

EARTHWORM ECOLOGY

Ecological Groups

Earthworm species can be grouped according to behavioral, morphological, or physiological adaptations that enable different species within earthworm communities to partition available resources. The three main ecological groups are termed epigeic, anecic, and endogeic.^[2,3] Epigeic worms feed on plant litter, dwell on the soil surface or within the litter layer, tend to be heavily pigmented, and are small to medium sized. Anecic worms feed on plant litter and soil,

live in permanent nearly vertical burrows, and are dorsally pigmented and large. Endogeic species are soil feeders, are not heavily pigmented, form extensive horizontal burrow systems, and range in size from small to large. Endogeic worms have been further divided into polyhumic, mesohumic, and oligohumic groups, which are separated, respectively, by the decreasing importance of organic matter in their diet and increasing size. Earthworm species do not always fall neatly into these three main categories and may even exhibit traits of different groups at different life stages or under different environmental conditions.

Earthworm Communities

Earthworm communities generally consist of one to six species. The relative abundance and species composition of earthworm communities depend on soil type, topography, and vegetation and are also influenced by land use history and earthworm biogeography. Earthworms account for the majority of animal biomass in soil in a wide range of productive ecosystems, from temperate grasslands, pastures, and forests to tropical pastures, savannas, and rain-forests, and many temperate and tropical agroecosystems. They generally do not occur in deserts and arid grasslands or in extreme alpine or boreal habitats. Earthworms are often absent from strongly acidic forest soils with poor litter quality, such as some northern coniferous forests.

Many earthworm communities consist of invasive exotic species. In North America, where approximately 100 native earthworm species have been described, at least 45 exotic species have been introduced. Lumbricid earthworms of European origin dominate many North American agroecosystems. A worldwide survey of earthworms in tropical regions reported that a total of 51 exotic and 151 native species commonly occur in tropical agroecosystems.^[4]

EFFECTS OF EARTHWORMS ON SOIL PROPERTIES

The influence of a given earthworm species on soil properties depends on the ecological group to which that species

belongs to. For example, the large vertical burrows of anecic earthworms, such as the common nightcrawler *Lumbricus terrestris*, can facilitate preferential flow of water through the soil profile and thereby increasing the transport of water, nutrients, and agricultural chemicals into deeper soil layers.^[5,6] Epigeic species facilitate the breakdown and mineralization of surface litter and can completely transform organic soil layers into a layer of earthworm casts. Anecic species incorporate surface litter deeper into the soil profile and can also bring soil from deeper soil horizons to the surface, which over a long period of time can change the mineralogy of surface soil. Endogeic species can facilitate a more thorough mixing of surface organic matter with mineral soil, and in some instances, in tropical soils the species can form compact casts that increase soil bulk density and decrease water infiltration.

Effects on Organic Matter Breakdown and Nutrient Cycling

Earthworm activity accelerates the decomposition of plant litter, increases rates of nutrient transformation and plant nutrient uptake, improves soil aggregation and porosity, and enhances water infiltration and solute transport. Earthworms can consume and incorporate large amounts of organic matter into soil (Table 1). Such mixing is largely responsible for the formation of mull soils in which surface organic horizons are thoroughly mixed with underlying mineral soil.

Earthworms have a major influence on nutrient cycling in many ecosystems. Although they generally increase the mineralization of soil carbon, earthworms can also decrease mineralization of carbon by contributing to the formation of stable soil aggregates in which carbon is protected from further breakdown. Direct fluxes of nutrients through earthworm biomass can be considerable. For example, the turnover of nitrogen (N) through earthworm tissues can be up to 150 kg N/ha/yr.^[3] Relative to surrounding soil, earthworm casts contain elevated amounts of nutrients including inorganic N. As a consequence, earthworms can greatly enhance the mineralization of N and can stimulate other N transformations such as denitrification.^[14] Much of the influence of earthworms on nutrient cycling can be

Table 1 Amount of organic matter ingested or incorporated into soil by earthworm populations in different environments.

Ecosystem	Location	Type of organic matter	Amount consumed or incorporated (kg/ha)	References
Maize field	United States	Maize residues	840	[7]
Orchard	England	Apple leaves	2000	[8]
Mixed forest	England	Canopy tree leaves	3000	[9]
Oak forest	Japan	Oak leaves	1071	[10]
Alfalfa field	United States	Alfalfa residues	1220	[11]
Tallgrass prairie	United States	Total organic matter	740–8980	[12]
Savanna	Ivory Coast	Total organic matter	1300	[13]

attributed to their interaction with soil microorganisms. Ecosystems with large earthworm populations tend to be characterized by faster cycling and bacterially dominated communities as compared to slower cycling and fungally dominated systems without earthworms.

Earthworms can also influence hydrologic fluxes of nutrients. By increasing bypass flow of infiltrating water, earthworm burrows can increase the amount of N and other nutrients leaching from the soil profile.^[5] Alternatively, earthworms can reduce the amount of nutrients lost in surface runoff by increasing the rates of water infiltration into the soil.^[15]

Effects on Physical Properties of Soil

The effect of earthworms on soil structure results from the net outcome of their feeding and burrowing activities. Earthworms ingest soil particles and organic matter, mixing these two fractions together and egesting them as surface or subsurface casts. Estimates of annual rates of production of earthworm casts range from less than 5 to over 250 Mg/ha in various ecosystems (Table 2). Once egested, soil in casts can be eroded due to the impact of rainfall or can form stable soil aggregates through a variety of stabilizing mechanisms.^[16]

Earthworms generally improve the aeration and porosity of soil through formation of burrows and by increasing the proportion of large aggregates in the soil, and their effects are especially important in poorly structured or reclaimed soil. By increasing the rates of water infiltration, earthworms can reduce the amount of surface runoff. Alternatively, earthworms can increase erosion by removing the protective cover of surface litter, increasing surface sealing,

and depositing surface casts, which can be carried down-slope during heavy rains. Some tropical species actually increase soil bulk density and decrease infiltration by producing compact soil casts. In general, the effects of earthworms on soil structure are considered to benefit soil fertility.

Effects on Plant Growth

The majority of studies examining the influence of earthworms on plant growth have reported that earthworms stimulate plant growth, although some studies have reported no effect or even a negative effect of earthworms on plant growth.^[2,17] Earthworms have been shown to increase the production of shoots and grain in a variety of field trials and greenhouse experiments. Introduction of earthworms into reclaimed polders in the Netherlands and in pastures in New Zealand resulted in large increases in forage quantity and quality.^[18,19] Beneficial effects of earthworms on plant growth may be due to increased nutrient and water availability, improved soil structure, and stimulation of microorganisms or formation of microbial products that enhance plant growth or possibly through direct production of plant growth promoting substances.^[17]

Undesirable Effects of Earthworms

Despite the documented and purported beneficial effects of earthworms on nutrient dynamics, soil structure, and fertility, some aspects of earthworm activities are considered undesirable.^[2] These include removing and burying surface residues that would otherwise protect soil surfaces from erosion; producing fresh casts that increase erosion and surface sealing; depositing castings on the surface of lawns and golf greens or irrigation ditches where they are a nuisance or in pastures where they interfere with haying operations; dispersing weed seeds in gardens and agricultural fields; transmitting plant or animal pathogens; increasing losses of soil N through leaching and denitrification; and increasing soil carbon loss through enhanced microbial respiration. Studies of earthworm invasions of north temperate forests in North America indicate that such invasion may have deleterious effects of native plant communities and contribute to loss of soil carbon.^[18] Clearly, there are instances in which earthworms can have undesirable effects, despite the fact that they are generally considered to benefit soil fertility.

EARTHWORMS AND SOIL MANAGEMENT

Influence of Agricultural Practices on Earthworm Populations

Earthworms can be affected favorably or adversely by different agricultural practices. Whereas heavy cultivation is

detrimental to earthworm populations, reduced and no-tillage agricultural practices promote their growth. Organic amendments, such as animal or green manures, also stimulate the growth of earthworm populations. Inorganic fertilizers may benefit earthworm populations by increasing the production of crop residues, but their effects are not as great as the effects of organic fertilizers, and the long-term application of inorganic fertilizers may adversely affect earthworm populations because of soil acidification or other changes in the soil environment. Liming can benefit earthworm populations in some instances.

Earthworms and Soil Reclamation

Introduction of appropriate earthworm species or encouraging natural population through the addition of suitable amendments can increase the rate of soil improvement and genesis of soil structure of reclaimed land. The introduction of European earthworms into pastures in New Zealand and Australia, as well as in Dutch polders, greatly facilitated improvements in soil structure and plant productivity.^[19,20] There has also been some success in introducing earthworms into reclaimed mining sites and in reclaimed peat with beneficial effects on soil structural development, nutrient cycling, and productivity.^[21]

Effects of Pesticides and Soil Pollutants on Earthworms

Pesticides have widely varying effects on earthworm populations, with many chemicals having little or no toxicity toward earthworms and others exhibiting acute toxicity.^[22]

In general, the carbamate insecticides and soil fumigants are very or highly toxic to earthworms. Herbicides, in general, show low toxicity toward earthworms, although there are some exceptions. Organochlorine and organophosphorus insecticides have varying levels of toxicity.

Soil contamination with organic pollutants, heavy metals, and acid precipitation can be detrimental to earthworm populations. Most toxic organic soil pollutants are highly toxic to earthworms. Heavy metals vary in their toxicity toward earthworms and can have acute as well as sublethal effects that include declines in earthworm growth and reproduction. This is also probably true of other soil pollutants but has not been well studied. Heavy metals can accumulate in earthworm tissues, increasing the risk of transfer of heavy metals to higher trophic levels, because of the wide array of animals that prey upon earthworms. Earthworm species vary in their tolerance of acid soil conditions, but some reports have noted a decline in earthworm populations in response to acid deposition.

Earthworms and Waste Management

Because they can consume large amounts of organic matter, there is an increasing interest in using earthworms to

process or manage organic wastes in a process known as “vermicomposting.”^[23] There are a limited number of large-scale commercial vermicomposting facilities operating at various locations throughout the world. The resulting compost material has been shown to have remarkably beneficial effects on plant growth in horticultural mixes.

CONCLUSION

The importance of earthworms to soil formation and organic matter breakdown has been recognized for a long time, and a global perspective has emerged that recognizes the complexity of interactions between earthworms and soil physical, chemical, and biological properties under different environmental, climatic, and edaphic conditions. The majority of research on earthworms has taken place in agricultural systems, and there is a need for more research in forests, natural grasslands, and other wildland ecosystems. With increasing interest in biodiversity and ecosystem function, and concern over biological invasions and global change, it will be important to evaluate how the introduction and spread of exotic earthworm species influence the conservation of native flora and fauna and modify valued ecosystem services, such as carbon storage, over time.

Eco-Agriculture

Norman Uphoff

Cornell University, Ithaca, New York, U.S.A.

Janice E. Thies

Department of Crop and Soil Sciences, Cornell University, Ithaca, New York, U.S.A.

Abstract

A number of related terms and practices get grouped under the rubric of “eco-agriculture” and its alter ego “agroecology.” While each approach has some distinctive characteristics and claims, all share a concern with the promotion and maintenance of *soil health* and with the *sustainability* of agricultural systems. Their holistic perspective emphasizes *connectedness* among elements within and between systems. Still, the processes and practices that these approaches favor are amenable to analytical treatment and for the most part to evaluation by accepted scientific methodologies. Trends in the 21st century—e.g., less arable land available per capita, lesser reliable water supplies for agriculture, continuing degradation of soil systems, and climate change—appear likely to make agricultural systems that were successful in the 20th century more amenable to, or even needing, revision in agroecological directions. Examples are given for profitable large-scale farming operations in Brazil, South Africa, and Pakistan that are moving agricultural production toward contemporary eco-agriculture.

INTRODUCTION

The designation “eco-agriculture” covers a number of related systems of agricultural practice, all of which are concerned with improving and/or maintaining the status and productivity of soil systems, while at the same time reducing negative environmental impacts. This term encompasses a dozen or more approaches to agricultural production that not only have some common elements but also some differences in emphasis or degree for certain practices.

A central concern in eco-agricultural approaches is the promotion and maintenance of *soil health*, sometimes characterized as “the life in the soil.” The health and fertility of soil systems are regarded as both a condition for and a result of eco-agricultural management. Another shared concern of all these approaches is *sustainability*.^[1] These approaches began focusing on sustainability challenges some time before they became a concern of policy makers and the general public.

A third concern in common is with the *connectedness* of agriculture, both with other sectors and of the many elements within agriculture. The sector is not regarded as isolated or autonomous. Reductionist modes of thinking do not dominate analysis and prescription. Rather, connections with the *natural environment*—to its soil, water, and biotic elements—and with *human beings*—their households, communities, and society—are identified and valued. The interdisciplinary subject of *soil ecology*^[2,3] is basic to all approaches to eco-agriculture.

Explicit consideration is given to the ways in which agricultural practice derives *benefits* from both the environment and society, while the *constraints* that emanate from each of these are also considered. The positive contributions that agriculture can make to natural ecosystems and to people’s well-being—when due attention is paid to ecological principles and opportunities—are highlighted. The *costs* that certain methods of agricultural management can impose on both the environment and humankind when the connectedness among natural and human factors is ignored or undermined are also considered.

The diverse but mostly compatible approaches within the domain of eco-agriculture are summarized in the following sections.

ORGANIC AGRICULTURE

Sir Albert Howard^[4,5] is generally regarded as the founder of the organic agriculture “movement,” based on years of research and experimentation in India. His propositions were reinforced by the writings of Lady Eve Balfour,^[6] which gave impetus to organic farming in the United Kingdom. In the United States, J.I. Rodale founded The Rodale Institute in 1930 to evaluate and demonstrate organic farming practices, launching the magazine *Organic Farming and Gardening* in 1942.

While this movement was often operationally defined by what is *not* done—no use of synthetic or inorganic fertilizers to increase the supply of plant nutrients in the soil, or

of agrochemical compounds to control pests and diseases—its main message was for farmers to provide organic matter to agricultural soils to enhance their functioning and fertility and to use beneficial insects and microbes and cultural control measures to manage pests and diseases. Organic agriculture is sometimes equated with eco-agriculture, but the latter is a more encompassing term.

AGROECOSYSTEMS/AGROECOLOGY

These perspectives have emphasized the operation of ecological principles and dynamics within agricultural production, parallel to and influenced by what occurs within the larger ecosystems within which agricultural activities take place.^[7] Both agroecosystems and agroecological analysis were proposed in the 1950s and 1960s, but by the 1990s, “agroecology” had become the more common rubric, in part because it came to cover a variety of approaches, some more biophysical and others more focused on social and economic concerns. Formative works on this subject include Altieri,^[8] Conway,^[9] and Gliessman.^[10]

ECO-AGRICULTURE

This term has been used to characterize the whole set of approaches considered in this entry; however, a specific use of the word has been introduced by McNeely and Scherr.^[11] These authors had respective institutional bases in the International Union for the Conservation of Nature and the Consultative Group for International Agricultural Research and have complementary disciplinary bases in conservation biology and agricultural economics. They have identified ways in which the respective aims of agricultural production and biodiversity conservation, as well as livelihood creation to benefit especially the poor, could be jointly achieved. This was seen as preferable to pitting these objectives against each other as has often occurred in both the conservation and agricultural development communities. A version of this known as *wildlife-friendly farming* in the United Kingdom has also been taken up in some other countries (<http://www.oursouthwest.com/farming/farming1.htm>).

SPECIFIC ECO-AGRICULTURAL SYSTEMS

A number of methodologies have combined certain practices that fall under the above-mentioned approaches. Each has encountered some controversy within academic and policy circles, but many practitioners have reported both yield and environmental advantages from these systems of practice:

- *Biodynamic agriculture* derives from the work of Rudolf Steiner, who, in a series of lectures in 1924 in what was then Germany (now Poland), proposed

organic preparations to enhance crop production along with green manures and cover crops, crop rotations, and other measures such as attention to astrological calendars. The association of biodynamic agriculture with Steiner’s philosophical and pedagogical beliefs gave this approach an aura of unscientific status, which limited its acceptance. A number of agronomic assessments have not supported claims of the methods’ superiority; however, there are national associations of biodynamic farmers in some 10 countries.

- *Biointensive agriculture* has been promoted by John Jeavons and others to attain maximum yields from a minimum area of land, seeking self-sufficiency and sustainability from given land areas.^[12] Much of the system derives from traditional agricultural knowledge and practices. More labor is required for double digging (deep digging) of the soil, intercropping, recycling organic materials, and making raised beds and compost. However, resulting yields can be very high. Biointensive agriculture can also include animals within the farming system although some versions focus solely on vegetable cropping. The effort to practice agriculture within a closed system, drawing on solar energy as the main or only external input, has made biodynamic farming controversial with many academic agronomists.
- *Permaculture* is an alternative agricultural system that establishes permanent agricultural areas along with permanent human settlements, seeking to capitalize on synergies among crops and animals. It utilizes polyculture and designs zonation and layers (stories) to organize productive relationships among crops, seeking to mirror naturally evolved ecological dynamics. The work of Smith^[13] was seminal for permaculture theory and practice, with the most widely used presentation being that by Mollison and Holmgren.^[14]
- *Natural farming* is the term describing a no-till, integrated cropping strategy developed and promoted by Masanobu Fukuoka in his influential book *One-Straw Revolution*.^[15] With the motto of “no machines, no fertilizer, and no chemicals,” Fukuoka was able to match or surpass average yields achieved with these purchased inputs although not the very highest yields obtained with them. This methodology was similar to what was called *nature farming* by Mokichi Okada in 1935, which also emphasized deep respect for nature. These practitioners have informed organic agriculture in Japan.
- *Holistic management* is similar to most of the above approaches but focuses on restoring degraded grasslands, managing land in concert with natural resources to reverse desertification and thereby achieve economic, environmental, and social benefits (<http://www.holisticmanagement.org/>). A summation of its practices was presented by Allan Savory.^[16] This strategy of intensifying and managing livestock to build up soil fertility is counterintuitive, but it has demonstrated empirical support.

TILLAGE-FOCUSED ECO-AGRICULTURE

The above-mentioned approaches have emphasized optimization in the mixes and management of *crops* (and/or live-stock), with attention to improved soil health and nutrient status. Other related approaches have focused on *reducing or eliminating tillage* as the basic feature of eco-agriculture. There is no inherent conflict between a focus on land preparation rather than on agronomic practices. However, this does lead to different presentations and somewhat different prescriptions:

- *Reduced till/zero till/no-till agriculture* represents an evolution of practice since the 1970s that has increasingly put into practice what soil scientists and farmers have known for a long time: that mechanical tillage has negative effects on soil health, structure, and function, disturbing and altering the soil biota.^[17] While there can be some short-term benefits of tillage—the most immediate being easier crop establishment and then weed control—there are adverse impacts on soil fertility and productivity over time: losses of soil carbon, shifts in the populations of soil organisms (numbers, diversity, and activity), and soil erosion. Consequently, increasing number of farmers have moved away from tillage, and there are more than 115 million hectares of agricultural land that are farmed without tilling.^[18] The movement to eliminate tillage has evolved into the following more comprehensive strategy of eco-agriculture.
- *Conservation agriculture (CA)* is a three-pronged strategy that starts with a *cessation of tillage*. It may be productive to break up subsurface hard pans by ripping where these have developed due to many years of intensive tillage, but this is not considered tillage, which mechanically changes soil structure repeatedly to create or prepare a seed bed. CA includes (in addition to minimized or no tillage) the *maintenance of permanent organic mulch cover on the soil* using crop residues and cover crops (including deep-rooted legumes) that halt erosion, improve water infiltration, and enhance soil nutrient contents and the *diversification of crop species grown in rotation or associations of crops* to enhance soil biodiversity and phytosanitation as well as to improve soil structure and function. The justification, sustainability, and spread of CA are presented by Kassam et al.,^[19] which show CA being practiced in all continents and ecosystems by large and small farmers alike. The Food and Agriculture Organization maintains a website on this beneficial soil management strategy (www.fao.org/ag/ca/).
- *Direct-seeded mulch-based cropping systems* is a version of CA developed by scientists with the *Centre Internationale de Recherche Agronomique pour le Développement* in Montpellier, France, from their work in various tropical countries although it is applied in

temperate ecosystems as well. Its methods for plant, soil, water, and nutrient management mimic the processes found in natural ecosystems for both productivity and sustainability.^[20]

SUSTAINABLE LAND USE

This is another focus of eco-agricultural theory and practice, usually driven more by practice than theory, particularly in response to crises of soil erosion or loss of soil fertility:

- *Landcare* is a programmatic approach to eco-agriculture, started in Australia in the late 1980s and formally recognized by the government in 1989, becoming a national movement with community, business, and government cooperation to control land degradation and deterioration of the hydrological cycle (http://en.wikipedia.org/wiki/Landcare_Australia). Better land use practices are expected to improve the “triple bottom line” of financial, environmental, and social gains. Landcare has spread to New Zealand, South Africa, the Philippines, the United States, Canada, and elsewhere. This is programmatic eco-agriculture with broad participation.
- *Agricultural stewardship* is a concept associated with the writings of Wes Jackson and Wendell Berry, having a broad philosophical as well as a pragmatic management orientation.^[21] Under this rubric, which originated in the United States but which is also gaining support elsewhere, most of the practices noted in the approaches summarized above can be promoted. Such an approach sustains often strong personal and organizational support such as seen in the Land Institute in Kansas (<http://www.landinstitute.org/>), the Prairie Plains Resource Institute in Nebraska (<http://www.prairieplains.org/>), and the Agricultural Stewardship Foundation in New York State (<http://www.agstewardship.org>). While there are scientific underpinnings for many of the practices recommended, this approach is driven more by observations and values than by scientific research.

Sustainable intensification, described as “low-input intensification” in a study commissioned by the European Parliament, is a restatement of eco-agricultural principles and strategies that has received endorsement from the scientific community and government circles in Europe.^[22,23] Previously, “intensification” was used to refer to *increased* use of external inputs to raise agricultural production. There is a growing understanding of how more intensive (vs. extensive) and ecologically informed management of available land, water, and other resources can increase farmers’ productivity in cost-effective ways.

THE FUTURE OF ECO-AGRICULTURE

There have been many conflicts surfacing between agriculture and the environment, with agriculture regarded as the greatest single threat to the conservation of biodiversity and with environmental protection seen as making agriculture less profitable and less viable. The different versions of eco-agriculture summarized here, however, see agriculture as part of the environment and as best practiced in consonance with ecological concepts and principles. Rather than accepting zero-sum (or negative sum) relations between the two domains, eco-agriculture undertakes to make this relationship a *positive sum* one, with aspirations of sustainability and equity alongside higher productivity.

During much of the 20th century, eco-agricultural approaches were contrasted unfavorably with “mainstream,” “modern,” or “conventional” agriculture, and most were regarded as marginal or alternative enterprises. Conditions in the 21st century, however, are likely to give more parity or even precedence to eco-agriculture. The continuing decline of arable land per capita, to one-third in 2050 compared to what it was in 1950, will reduce the comparative advantage of large-scale, mechanized agriculture, and higher energy costs will make energy-intensive production methods less competitive economically. Higher transportation costs will make long-distance trade in agricultural products less profitable.

Climate change together with growing scarcity and unreliability of rainfall will further disadvantage some of the more “thirsty,” monocropping technologies. Increasing concern with soil and water quality and with environmental health will make heavy reliance on inorganic fertilizers and agrochemical means of crop protection less tenable. The technologies and factor proportions that have prevailed in the 20th century are likely to warrant reconsideration in the future.

There is no longer justification for the stereotype of eco-agricultural methods as old-fashioned and suitable only for small-scale production. The following examples from three continents show how it can be innovative and forward-looking.

Brazil

The Balbo family's sugar enterprise began converting to organic production in 1986. By 1997, 14,000 ha of its 20,000 ha plantation were certified as “organic.” Three hundred smaller producers supply cane to the factory from another 24,000 ha. Together they grow and process 6.1 million tons of cane, producing 300,000 tons of crystal sugar and 320,000 m³ of fuel ethanol annually. The factory operation has become entirely self-sufficient for energy, and the farm operation will soon be meeting all of its energy needs, so that the whole enterprise is carbon neutral.^[24]

Both efficiency and profitability are achieved through recycling of organic matter, improvement of soil health,

integrated pest management, and biological control for insects and weeds. Sugar plantations are usually some of the least biodiverse areas to be found. Yet a five-year evaluation by researchers from the Brazilian national agricultural research authority EMBRAPA documented on the plantation's 79 km² over 300 species: 230 bird species, 26 kinds of amphibians, 17 species of reptiles, and 39 different mammals, including jaguars and pumas at the top of the food chain. Many of these are rare, and none were stocked; all returned naturally once the plantation was redeveloped to contain diverse habitats compatible with efficient sugarcane production. The Balbo enterprise supplies one-third of the world's consumption of organic sugar, and its products are exported to 60 countries (<http://www.nati vealimentos.com.br/pt-br/>).

South Africa

ZZ2, a multisystem farming conglomerate located primarily in the Limpopo Province, has grown from a subsistence farm to the largest producer of tomatoes in sub-Saharan Africa. It registered as a private company in 1966 and produces tomatoes, onions, avocados, apples, pears, and beef, primarily, exporting some of these commodities to Europe, the Middle East, Canada, and neighboring African countries. The bulk of its production is consumed domestically, however, as ZZ2 supplies 30% of the domestic market's tomatoes. The enterprise manages 60,000 ha of land, of which 10,000 ha are used to produce food. The remaining area is used for conservation through private game conservancies, to ensure water resources, and to fallow (rest) productive lands between crops as unimproved pasture.

In the late 1990s, ZZ2 began to experience declining yields despite increased use of fertilizers and pesticides and operating a seven-year pasture rotation between tomato crops. Various consultants helped the farm managers understand that their fundamental problem was degraded soil. In 2002, to restore and then maintain soil fertility, the firm embarked on a “nature farming” approach (Natuurboerdery[®]), applying more organic inputs and fewer agrochemicals. ZZ2 has moved away from industrial agricultural practices and toward the use of compost, compost teas, fermented plant extracts (FPEs), and effective microorganisms as alternative fertilizers and/or pesticides. It relies primarily on green technologies, using biocontrol agents such as *Trichoderma*, arbuscular mycorrhizal fungi, FPEs, and compost teas. Average tomato yields per hectare, which were declining steadily year by year, have stabilized at 77 tons ha⁻¹ in 2009; although when initially converting to Natuurboerdery, ZZ2's tomato production was reduced in the early years of the transition. The existing system is demonstrating both profitability and sustainability (http://www.zz2.biz/index.php?option=com_content&view=article&id=19&Itemid=23).

Pakistan

FarmAll Technology Ltd. has been one of the leading companies for agricultural mechanization in this country, importing and distributing tractors and other equipment from major foreign producers over since 1980s, as well as manufacturing Ford and Ursus tractors. FarmAll was the first operation to laser-level agricultural fields to reduce water requirements. It has developed machinery for the otherwise labor-intensive system of rice intensification (SRI), reducing both labor and water requirements while getting higher yield. Its 2009 trials on an 8 ha plot averaged 13 tons ha⁻¹ with 70% less water and labor. The transplanting and weeding machinery used for rice has been adapted to other crops (wheat, potatoes, and a wide range of vegetables) with similar cost savings and higher yield.

FarmAll is synthesizing SRI methods (younger seedlings, reduced plant populations, no flooding of the fields, and active soil aeration) with CA (permanent raised beds with soil cover) and with organic agriculture (precision application of organic matter, sometimes supplemented with small amounts of synthetic fertilizer). FarmAll's general manager Asif Sharif calls this "paradoxical agriculture" because the combination of practices enables the company to produce more agricultural output with reduced inputs by utilizing ecologically based principles (<http://www.farmalltechnology.com/>).

These enterprises utilize modern science and technology within a framework of theory and practice that utilizes ecological principles and perspectives with the goal of making agriculture both more productive and more sustainable. These complex farming systems represent a synthesis of agricultural and ecological knowledge that can revise and mitigate the widespread tensions between them.

Ecology: Cycling of Carbon and Nitrogen

Alan J. Franzluebbers

U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS),
Watkinsville, Georgia, U.S.A.

Abstract

Carbon (C) is found throughout nature in a wide variety of forms and particularly in soil. Nitrogen (N) is an essential element of plants, animals, and microorganisms, which is a part of chlorophyll, enzymes, amino acids, and proteins, which are necessary for the growth and development of organisms. C and N occur in various forms and undergo transformations from one form to another. This entry reviews the environmental influences on these cycles.

INTRODUCTION

Carbon (C) and nitrogen (N) are two of the most important elements that affect the soil's productivity and environmental quality.^[1] C is found throughout nature in a wide variety of forms and particularly in soil as 1) complex organic compounds (e.g., $C_xH_{2x}O_x$) derived from living organisms; 2) carbonate minerals such as calcite ($CaCO_3$) and dolomite ($CaMg(CO_3)_2$); and 3) carbon dioxide (CO_2) and methane (CH_4) as decomposition end products. N is an essential element of plants, animals, and microorganisms, which is a part of chlorophyll, enzymes, amino acids, and proteins, which are necessary for growth and development of organisms. In soil, the quantity of N in organic matter and as clay-fixed ammonium (NH_4^+) far exceeds quantities in plant-available forms of nitrate (NO_3^-) and NH_4^+ .

C AND N CYCLES

C and N occur in various forms and undergo transformations from one form to another, primarily through biochemical manipulations involving enzymes.^[2,3] Enzymes are catalysts of very specific reactions that function either 1) intracellularly within plants, microorganism, or soil animals or 2) extracellularly in soil solution or attached to soil colloids.

The forms and fluxes of an element are commonly illustrated in a cycle following the principles of conservation of mass (i.e., elements are transferred from one molecule to another). The C and N cycles have global dimensions with terrestrial, aquatic, and atmospheric components of major significance.^[4,5] The sun initiates a chain of energy reactions, which drive elemental cycles. The elemental cycles of C and N interact closely with the water cycle, as water is a fundamental internal component of life and a major transport mechanism of nutrients.

Autotrophic fixation of atmospheric CO_2 by plants captures the energy of the sun within organic compounds via the process of photosynthesis (Fig. 1). Inorganic N is taken up by plant roots and synthesized into amino acids and proteins during plant development. Plants are eventually consumed by animals or microorganisms, transferring portions of this stored energy through biochemical processes into various cellular components. Once in soil, the C cycle is dominated by the heterotrophic process of decomposition, i.e., the breakdown of complex organic compounds into simple organic constituents. Mineralization is the complete decomposition of organic compounds into mineral constituents:

Immobilization of N occurs simultaneously with N mineralization when soil organisms consume inorganic N to meet the demands for new body tissue. Net N mineralization occurs when gross N mineralization exceeds that of N immobilization.

ENVIRONMENTAL INFLUENCES ON SOIL MICROBIAL ACTIVITY

The dominant organisms responsible for the decomposition of organic matter and associated mineralization of C and N are soil microorganisms, composed of bacteria, actinomycetes, fungi, and protozoa.^[6,7] Soil fauna also indirectly affect C and N cycling by 1) comminuting plant residues and exposing a greater surface area to soil microorganisms; 2) transporting plant and animal residues to new locations in the soil to facilitate decomposition, interaction with soil nutrients, or isolation from environmental conditions; 3) inoculating partially digested organic substrates with specific bacteria and enzymes; and 4) altering physical

Fig. 1 Generalized diagram of the C and N cycles in soil.

characteristics of soil by creating burrows, fecal pellets, and distribution of soil particles that influence water, air, nutrient, and energy retention and transport. With suitable environmental conditions, soil microorganisms grow rapidly in response to the availability of organic substrates rich in C and N.

Soil Temperature

Temperature controls both plant and soil microbial activity, although not at the same level (Fig. 2). Plant and soil microbial activity are limited by low temperature, resulting in low photosynthetic potential, as well as low decomposition potential. For many plants, net photosynthetic activity is optimized between 20°C and 30°C, because at higher temperatures plant respiration consumes energy for maintenance. In many temperate soils, microbial activity is maximum near 30°C and decreases at higher temperatures. An intermediate temperature is often ideal for maximizing C retention in soil, where optimum plant activity outdoes soil microbial activity.

Soil Water Content

The greatest diversity of soil microorganisms is found under aerobic conditions, where maximum energy is obtained. However, there are a number of soil bacteria that thrive under anaerobic conditions, in which alcohols, acetic acid, lactic acid, and CH₄ become C end products via fermentation, and NO₃⁻ is converted to N gases (e.g., N₂, N₂O, and NO) via the process of denitrification. Soil C mineralization and net N mineralization are maximized at an

optimum balance between soil moisture and oxygen availability (Fig. 3). Significant denitrification occurs at water-filled pore space > 70%, resulting in what appears as reduced net N mineralization.

Soil Texture

Soil texture can influence the quantity of both C and N accumulation in soil and their potential mineralization. Potential C mineralization is often greater in coarse-textured than in fine-textured soils, which may be due to both increased microbial predation by soil fauna and greater accessibility of organic substrates in coarse-textured soils. Organic C and N can also be protected from decomposition when bound within soil aggregates, which are a coherent assemblage of primary soil particles (i.e., sand, silt, and clay) cemented through natural forces and substances derived from root exudates and soil microbial activity.

Spatial Distribution of Organic Substrates

Distribution of organic substrates in soil has a major impact on potential C and N mineralization. Potential C mineralization is often several fold greater in the rhizosphere (i.e., 0–5 mm zone surrounding roots) than in bulk soil. However, because of the high demand for N by plant roots and the stimulated soil microflora, net N mineralization is often lower in the rhizosphere because of immobilization of N.

The soil surface often contains greater quantities of organic matter than at lower depths due to surface deposition of plant residues, as well as highest plant root

Fig. 2 Typical responses of plant and soil microbial activities to temperature.

activity. The soil surface usually undergoes the most extreme drying/wetting cycles and has the greatest exchange of gases, both of which contribute to enhanced soil microbial biomass and activity. Tillage of soil with traditional agriculture redistributes the organic substrates uniformly within the tillage layer, often resulting in stimulated soil microbial activity from the disruption of organic substrates protected within stable soil aggregates. Minimum soil disturbance with conservation tillage practices can reduce oxidation of soil organic matter and preserve more C within soil, which can have implications for potentially mitigating the greenhouse effect.^[8]

Fig. 3 Responses of potential soil C and N mineralization to water-filled pore space in Typic Kanhapludults in Georgia, the United States. Air-filled pore space is 100 – (water-filled pore space).

ORGANIC SUBSTRATE QUALITY

The quality of organic substrates has a major influence on the rate of decomposition and the transformations that occur in soil. Plant residues do not vary greatly in total C concentration on a dry weight basis (e.g., 37–47 mg g⁻¹), but do vary in the suite of C compounds, which determine its quality or conversely its resistance to degradation. The diversity of organic compounds attacked by soil microorganisms is extensive (e.g., organic acids, polysaccharides, lignins, aromatic and aliphatic hydrocarbons, sugars, alcohols, amino acids, purines, pyrimidines, proteins, lipids, and nucleic acids). Almost all naturally occurring organic compounds, and even most synthetic organic compounds, are susceptible to decomposition, given the appropriate environment, microbial community, and time.^[9,10] Generally, the primary components of plants can be categorized according to the relative rate of decomposition: rapid (sugars, starches, fats, and proteins), intermediate (cellulose and hemicellulose), and slow (lignin and lignocellulose). Young plants are of high quality and low resistance to decomposition, whereas with aging, lignin and polyphenolic concentrations increase, resulting in greater resistance to decomposition. Low N concentration of organic amendments usually results in temporary net N immobilization into microbial biomass, which grows rapidly in response to the availability of organic C. Soil microbial biomass maintains a C/N ratio of 10±5. Following a proliferation of microbial biomass that depletes the source of readily decomposable organic C/N in excess of microbial demands becomes mineralized and available for plant uptake (Fig. 4). In general, plant residues with C/N ratio > 40 will result in longer periods of net N immobilization.

Fig. 4 Typical responses in soil microbial activity and soil NO_3^- concentration with the addition of plant residue relatively low in N concentration.

Soil Organic Matter

Soil organic matter is composed of a large variety of organic compounds that can be characterized in many ways. A useful separation of soil organic matter for modeling is based on the turnover times, whereby at least three pools can be defined: 1) active (composed of microbial biomass and light fraction material with a turnover time of < 1 year); 2) passive (composed of macro-organic matter and protected organic matter with a turnover time of 3–10 years); and 3) slow (stable humus fraction with a turnover time of > 100 years).

LOSSES OF N FROM SOIL

N cycling in soil is different from that of C because of the more numerous transformations that can occur upon mineralization to an inorganic form.^[11] Mineralization of N from organic matter results in NH_4^+ released into soil solution. In the presence of nitrifying bacteria, NH_4^+ is converted to NO_3^- , a process called nitrification. The fate of NO_3^- in soil depends on environmental conditions. Active plant growth in natural and agricultural systems would provide enough demand to re-immobilize N into organic forms. However, NO_3^- can be used as an electron acceptor in place of O_2 under anaerobic conditions with a supply of soluble organic C, resulting in gaseous loss of N to the atmosphere via denitrification. In temperate soils with a net negative charge on colloidal surfaces, NO_3^- can readily leach into the vadose zone and contaminate groundwater. In tropical soils with a net positive charge, NO_3^- can be retained on anion exchange sites. Contradicting behavior of the cations, NH_4^+ and NO_3^- , occurs with respect to clay mineralogy.

Humans, as well as roving animals, impose great demands on the C and N cycles. Management of agricultural and forest land for food and fiber removes nutrients from soil for consumption and utilization elsewhere. Return

of these nutrients to soil is possible when municipal and agricultural solid wastes and wastewater are applied to land. Losses of C and N from managed lands also occur through soil erosion, which transports nutrients via 1) water from overland flow into streams, lakes, and oceans; and 2) air from exposed land.

Volatilization of ammonia (NH_3) to the atmosphere is possible when NH_4^+ is exposed to alkaline soil conditions. Significant NH_3 volatilization can occur with surface application of urea fertilizer to non-acidic soils, from animal manures, and from green plant materials not incorporated into the soil.

FIXATION OF C AND N

Both C and N are biologically fixed from inorganic atmospheric forms to organically bound plant and microbial forms. As mentioned earlier, photosynthesis converts CO_2 from the atmosphere into organically bound forms in plants, algae, and cyanobacteria. Biological N_2 fixation is a unique transformation carried out by a number of bacteria, which convert N_2 gas into NH_3 for biological uptake. These bacteria are most prevalent in symbiotic relationships with plants, such as *Rhizobium* that forms nodules on the roots of clovers where the nitrogenase enzyme catalyzes the reaction. Fertilizer manufacturing converts N_2 gas into NH_3 in a similar manner without an enzyme, but rather large quantities of energy necessary to create the pressure required for the transformation.

Under certain conditions, both inorganic C and N can be chemically fixed in the subsoil. CO_2 forms carbonic acid in water, which can precipitate with the basic cations, Ca^{2+} , Mg^{2+} , and Na^+ , to form pedogenic carbonates. Inorganic C is most abundant in soils of the semiarid and arid regions. NH_4^+ can be fixed as non-exchangeable components of the lattice structure of 2:1-type clay minerals, which are especially prevalent in the subsoil of many younger soils.

Economics of Soil Management: U.S.

Jeffrey W. Hopkins

Resource Economics Division, U.S. Department of Agriculture—Economic Research Service (USDA-ERS), Washington, District of Columbia, U.S.A.

Abstract

Economists have a long and continuing tradition of evaluating soil management practices as they affect soil fertility and soil degradation. But economists realize that, in practice, soil management techniques are applied only to the point where the farmer (or society) is better off economically. Because economics considers all inputs and outputs of soil management, including off-site impacts, the environmental impacts of soil management demand constant study as well. Therefore, an economic assessment of soil management must extend beyond the farm field to consider off-site effects on water, air quality, and wildlife habitat.

INTRODUCTION

The economics of soil management differs from the physical science of soil management—it looks at maximizing long-run economic return, rather than maximizing soil performance and quality. With regard to maximizing soil performance, the prescription from soil scientists is clear and can be summarized as follows: add organic matter, avoid most tillage and other activities that might erode or compact the soil, apply chemicals on an as-needed basis, and keep the ground covered between growing seasons; increase crop diversity across a landscape; and systematically monitor soil chemical and physical properties.^[1]

ECONOMIC EVALUATION OF SOIL MANAGEMENT PRACTICES

Soil Fertility Management

Starting in the 1950s, economists used static production functions to formulate soil fertility recommendations, relying heavily on data generated by soil scientists and agronomists on crop yield response to soil management practices.^[2–4] Economists have since sought improvement over the single-period crop soil management recommendation by searching for solutions that increase both existing and future profits. In cases in which a dynamic biological process is considered, such as fertilizer carryover,^[5] or crop response to management is highly variable,^[6] multi-period analysis has proven to be particularly important. In the 1990s, with advances in computer, positioning systems, and application technology, many producers, as well as scientists, have become interested in managing spatial variability within a field.^[7] Economic management of site-specific soil conditions requires significant knowledge about the variability of soil properties and how these impact

crop response. While the relative profitability of site-specific soil management is unproven, some studies have shown that modest improvements in economic return can be achieved.^[8,9]

Soil Degradation Management

Soil fertility research finds ways to increase yields; soil degradation research looks for soil management techniques to keep crop yield growth from leveling off. In the United States, water and wind erosion and soil compaction remain the primary soil degradation concerns^[10] despite a 38% decrease in cropland wind and water erosion from 1982 to 1997.^[11] Soil erosion decreases potential crop yield by depleting soil nutrients and topsoil depth. Some have argued that it is the latter effect that poses the greatest threat to future food security.^[12] Because the rate of soil genesis is so low, topsoil losses are often considered irreversible and, therefore, of particular concern. This argument has apparently been particularly persuasive in the United States, where conservation policy abandoned an earlier recommendation to limit degradation to “tolerable” nutrient losses and, instead, focused exclusively on limiting degradation to “tolerable” losses of soil depth.^[13] However, U.S. irreversible topsoil losses have been shown to be slight in aggregate,^[14] especially when viewed in relation to past yield increases from improvements in technology and management.

Off-Site Impacts of Soil Management

Except for doubts regarding the ability to continue to achieve productivity gains that doubled world grain harvests since 1960,^[15] conventional thinking among economists is that the downstream costs of poor soil management (borne by users of downstream surface water) are larger

than the combined costs of on-site productivity losses and future food security.^[16] To decrease the likelihood of both social and private costs from non-optimal soil management, U.S. conservation policy has promoted farmer adoption of soil-enhancing practices. These *best management practices* hold the promise of a win-win solution for farmers and society at large. However, farmer adoption is far from universal for any single practice.

ADOPTION OF SOIL MANAGEMENT PRACTICES IN THE UNITED STATES

The adoption of most agricultural innovations has been shown to depend on both *farm* and *farmer* characteristics. The experience of U.S. hybrid corn adoption is instructive in understanding why best management practice adoption may not be universal. While hybrid corn was especially quick to catch on in Iowa, the adoption of open-pollinated corn elsewhere was in part limited by the availability (different hybrids appeared in different parts of the country) and acceptability (some farmers were reluctant initially) of the technology.^[17] The adoption of soil-based best management practices is likewise limited to factors related to the farm (climate and soils) and the farmer (firm management and household characteristics). The following material examines soil performance characteristics and on-farm adoption patterns of three best management practices—namely conservation tillage, monitoring soil properties, and crop rotations.

Conservation Tillage

Conservation tillage is a system of crop production that leaves additional crop residue remaining on the field after harvest to decompose naturally. Conservation tillage can increase soil organic matter and, therefore, increase soil productivity by increasing moisture retention and improving soil tilth. It can also drastically decrease soil erosion levels compared to conventional tillage methods and similarly reduce some rates of nutrient loss, particularly phosphorus. While the adoption of practice (defined strictly as 30% or more of the soil surface covered with flat and standing residue) grew steadily through the 1970s until the mid-1990s and is growing for some crops, overall adoption has hovered at 35–37% of U.S. planted cropland, according to field surveys.^[18,19]

The adoption rate of conservation tillage follows a regional distribution, with the highest rate (about 50%) among corn and soybeans producers in the Corn Belt and lower adoption rates (about 10%) by cotton and small grain producers in the West.^[20] While the adoption of conservation tillage can result in stable or increased crop yields compared to conventional systems, as well as decreased input costs (primarily machinery, chemical, fuel, and labor costs), these savings are not always seen in practice.^[21]

Any absolute economic advantage is likely derived only after several years of use of the system and may still be slight unless multiplied over many acres. In 1995, conservation tillage adoption rates on farms with sales greater than \$100,000 were more than 50% higher than on smaller farms.^[22]

Monitoring Soil Properties

Monitoring soil chemical and physical properties through soil testing can provide valuable information to farmers, allowing them to more closely match soil conditions with soil requirements for the growing crop. Optimal use of monitoring technology allows farmers to match soil conditions with crop-growing requirements both temporally (such as splitting nutrient applications into two smaller doses rather than one large dose) and spatially (dividing a field into different management units depending on soil conditions). The adoption of soil monitoring varies by the soil property monitored (20% of all cropland is tested for nutrient levels) and is the greatest in high-value crops, particularly fruit, vegetables, and cotton production.^[20] Site-specific soil management systems include spatially monitoring crop yield and soil quality as well as spatially applying inputs. The on-farm adoption of site-specific management has been less widespread than the soil performance gains suggest, with less than 1% adoption across all farms in the United States. The adoption of some components, such as intensive soil sampling, has appealed to certain types of farms, however, with corn and soybean producers (11% adoption) and high sales farms (18% adoption for farms with sales greater than \$500,000) among the early adopters.^[23]

Crop Rotations

Crop rotations allow producers to increase soil organic matter and reduce soil erosion, although these soil performance improvements are most likely to occur when row crops are rotated with hay, meadow, or pasture. In 1997, while 80% of cropland was grown in some sort of rotation, only 3% of acreage followed the hay, meadow, or pasture rotation reported to maximize soil performance.^[20] The economic role of crop rotations may be different from the physical role. For corn producers, crop rotations are particularly popular with both very large farms (with more than \$250,000 in sales) and with part-time farmers.^[22] For large farms, rotations could play a role in managing busy planting and harvesting periods, while for part-time farmers the role may be in managing on-farm and off-farm employment. Low use of hay rotations for row crop producers may be an indication that few producers are willing to forego any row crop sales in favor of greater soil performance. Cover crops, which do not occupy a full growing season, can effectively increase soil organic matter and decrease erosion, while still allowing farmers to produce the crop giving highest economic return. Cover crops, however, are

used rarely outside of the South, where the practice is common with soybean production. In this system, some cash gain can be achieved in double-cropping winter wheat or rye.^[20]

IMPLEMENTING SOIL MANAGEMENT PROGRAMS IN THE UNITED STATES

In cases in which the off-site costs of suboptimal soil management are great, such as where soil and nutrient runoff cause water quality problems, additional economic incentives have been used to increase the adoption of a best management practice. For example, the Environmental Quality Incentive Program, administered by the U.S. Department of Agriculture, provides technical assistance and extension education, as well as cash payments to producers adopting certain best management practices. The program is unlike earlier soil management initiatives because it targets participation to maximize the environmental benefit per dollar spent on the program. In most cases, encouraging adoption first in those areas where off-site damages can be decreased cheaply is an improvement over programs that solely attempt to increase adoption in general. No matter how programs are targeted; however, increasing the existing size of the pool of adopters has come at increasing cost.

Because improved practices have costs as well as benefits, economists advise a farmer who invests in soil performance to do so selectively, with an eye toward balancing the costs of improving soil performance with the long-term economic opportunities afforded by the practice. In general, however, the cost to producers of an improvement in soil performance is usually more clear than the benefits, which are realized in the future. To address the uncertainty of benefits relative to costs, producers will continue to need information on how to profitably improve soil management.

Ecosystems: Life Attributes and Environment

Dennis R. Linden

Soil Water and Climate Department, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), St. Paul, Minnesota, U.S.A.

Abstract

Soil is the home for plant roots and organisms of a wide variety of types and sizes, and soil ecology is the science of linkages between life attributes and the life-supporting environment. Life attributes involve an individual organism or group of organisms, their interaction with other organisms or groups, and direct or indirect functions or reactions. Soil life is supported in a porous lattice of mineral matter, living and dead organic material, water and its dissolved and suspended constituents, and soil air. The spatial scale of concern for soil ecology might be the microscopic environment of a few unicellular organisms or the expansive reaches of a particular soil or vegetation type. The temporal scale of concern might be the microsecond of a chemical or biological reaction to the eons of soil-profile development. It is thus visualized as a wide-ranging discipline made even more complex by the intricacies of the dynamic soil environment.

COMPOSITION AND NATURE OF SOIL

Soils are composed of minerals, living and dead organic material, air, and water arranged in a complex matrix. The minerals and organic material form a semirigid lattice, which leaves voids that are occupied by water and air. Air and water are usually free to exchange so that the void space that is not occupied by water is occupied by air. Water is a bipolar molecule and is held, at strengths that decrease with distance, to the exposed surfaces of the lattice. Under a given temperature regime, it is the balance between air and water and the composition of the solution and the air that exerts the most control of the life-supporting soil environment.

LIFE ATTRIBUTES AND THE SOIL ENVIRONMENT

Some of the terms that describe life and life functions (life attributes), and terms that describe the controlling environment are listed in [Table 1](#). Attributes ranging from the presence of a single organism to a collection of organisms and reactions such as N fixation are shown as examples of the attribute side of ecology. Water content, pH, CO₂ concentration, and temperature are examples of the environmental limits of ecology.

An important example will clarify the definition of soil ecology. The process known as denitrification results in the conversion of nitrogen (N) from bound forms to nitrous oxides that are gaseous and easily lost from the soil environment. The lost N may have been beneficial to many organisms, especially plant roots, and

its loss may contribute to the emission of a greenhouse gas. This process, however, is a major source of energy for a particular group of soil organisms. Energy is released when hydrogen atoms bonded to N are replaced with oxygen, and when oxygen is removed to form gaseous nitrous oxide or N gas. This process requires both an aerobic step where oxygen from the air replaces the hydrogen bonded to N atoms and an anaerobic reaction where oxygen from nitrate is stripped away from the N atom in the absence of oxygen in the air. This complex sequence of microbial-driven biochemical reactions thus supports both an aerobic and an anaerobic group of organisms that may occupy only slightly different niches within short distances in a soil. Soil ecology may only be interested in the step-by-step process or in the overall outcome of the system.

THE DYNAMICS OF WATER AND AIR

Soil–water content is the most important soil environmental factor of the soil ecosystem. Water has a direct effect on most life attributes, and water content is often indirectly related to properties of the air and the semirigid matrix. The dynamic nature of soil water and its importance to life attributes are imbedded in the concept of “least limiting water content.” As soils become drier by evaporation or by root uptake and translocation, the water remaining within the soil is sorbed by roots or other organisms with more difficulty. Eventually, soils will become so dry that most life ceases or becomes dormant. Drier soils also strongly resist deformation that is necessary for root growth and displacement by burrowing animals. When soils are

rewetted, the cycle of life is renewed. Prolonged wet soils restrict the movement of air and often become oxygen depleted. Intermittently, wet soils are common and usually do not result in a serious depletion of oxygen. Soils that remain wet because they are continually supplied either with water such as under a pond or from a shallow water table, or that has an internal layer, which restricts the outflow of water may also become oxygen depleted. These conditions support only those life attributes that do not require oxygen from the atmosphere. Soils vary in their ability to absorb and hold water at both the dry and wet ends of the water-holding spectrum. The size and packed arrangement of particles control the relative

spaces available to transport or retain water. Clays and organic material are largely responsible for a soil’s ability to hold water, while sands and aggregated particles provide for the spatial voids for liquid and gas transport. A given soil with a known composition of sand, silt, and clay can be subjected to considerable packing variability depending on its history of perturbations. A loose soil that allows water entry and free drainage, while retaining some water to support life may become compact, nearly impermeable, or water logged due to compacting traffic. The reader is referred to those sections describing soil water for a more detailed discussion of this important dynamic aspect of soil.

SOIL TEMPERATURE

Soils transmit and store heat. Thus, soil temperature will rise and fall depending primarily on the temperature and radiation conditions of the atmosphere directly above the soil. As temperatures rise and fall on either daily or seasonal cycles, the activities of soil organisms also rise and fall. Activity is influenced by both the extremes of the short-term cycles and the long-term patterns of soil temperature. Most soil activities exhibit a response to temperature that would begin low, rise to optimum, and then decline as temperature increases. The range and optimum soil temperatures for a life activity are uniquely characteristic of different organisms. Either cold or high temperature may be lethal to an organism. Soil temperature varies most at the soil surface, where daily swings might exceed 25°C, and varies less with increasing soil depth. As the soil is home to a multitude of organisms, the capacity to respond to changes in soil temperature is another unique aspect of the soil ecosystem. Cold soils in the winter have little activity, but it rises as temperatures increase. High summer temperature might lower the activity of many organisms, but their activity will increase again as temperatures decline in the fall. Soil-temperature fluctuations are highly linked to soil–water conditions because soil–water provides a large proportion of the soil’s capacity to store heat and because soils cool as water evaporation removes heat. There is usually a web of organisms somewhat unique to a soil’s temperature regime. For example, warm tropical soils support a much different group of organisms than temperate or arctic soils.

BUFFERED AND PROTECTED ENVIRONMENT

The soil is an ecologically rich environment because of its high capacity to protect organisms and to buffer them against changes in environmental conditions. Soils absorb, store, and slowly release water, heat, nutrients, and organic materials that provide the life-sustaining needs of organisms. Organisms within the soil are protected from the sudden and sometimes catastrophic changes occurring aboveground.

AGRICULTURAL CHEMICALS

One of the most important management interactions with the soil ecosystem comes from chemicals that are used to enhance or inhibit specific life functions. Chemicals used in agriculture and forestry fall into two categories. Essential plant growth nutrients that may be supplemented through chemical additions. This is a very common practice and often has little direct effect on organisms or their function. However, these nutrients may strongly influence the biochemical

reactions within soil organisms. The second class of agricultural chemicals is pesticides used to inhibit the activity of specific plant or animal pests. Weed and insect control are common agricultural practices. Pesticides come from a variety of chemical compounds and their action ranges from inhibiting a specific organism to a general biocide.

Other chemicals that influence life functions may occasionally occur in soils. Petroleum spills and heavy metals are two examples of these occasional chemicals. In general, chemicals of this nature are not beneficial to soil life and may be directly harmful. An emerging field of science is matching organisms of specific genetic capability to degrade and thus remove these contaminants from soil.

TILLAGE

The state of a soil may be drastically changed by mechanical disturbance. Tillage of some form is a common practice in agriculture in order to improve the seedbed, control weeds, bury crop residues, or incorporate chemicals. Tillage thus suddenly produces a new arrangement of solid, liquid, and organic materials, which results in a shift of soil activity. Tillage has an effect on most of the soil properties that control the water, oxygen, and temperature dynamics within the soil. Tillage also will often break open aggregates or clods exposing the interior soil, which had been somewhat isolated, to a fresh oxygen-rich atmosphere. Two-known consequences of this breakage are flushes of carbon dioxide released to the atmosphere and N released into the soil solution as organic matter is degraded by soil organisms.

THE IMPORTANCE OF SOIL ECOLOGY

Soil ecology is important to the expected performance of a soil in many respects because of the varied forms of life within the soil. A list of organisms, however, does not fully identify this importance as we are primarily interested in the processes performed rather than the organisms. Carbon and N cycles that are driven by organisms within the soil are important for production of crops and forests, safeguarding the environment, maintaining soil quality, and to global warming. Nutrient cycling from decaying matter into new life is essential to maintaining that life and is an important function studied under soil ecology. Many diseases and pests are strongly influenced by the soil environment and they are often a major economic factor of production. Plant roots are only part of a living organism, but their function in nutrient and water uptake is critical to support life. The soil environment and the

organisms near plant roots are an especially important region of soil, known as the rhizosphere. Because of its importance, the rhizosphere is the subject of as much work in soil ecology as all other subjects combined. The reader is referred to sections of this encyclopedia for additional detail concerning these important aspects of soils.

Enchytraeidae

María Jesús Iglesias Briones

Department of Animal Ecology and Biology, University of Vigo, Vigo, Spain

Abstract

Enchytraeid worms constitute a little known group of soil mesofauna because of their small size and the difficulties associated with their identification. They are commonly the most abundant invertebrates in high organic soils and frequently comprise over 70% of the soil faunal biomass. Their populations usually concentrate in the upper soil layers where they feed on a mixture of dead organic matter and microorganisms. They are known to be ecosystem architects that increase soil aeration by burrowing and have important effects on nutrient cycling.

INTRODUCTION

Enchytraeidae (potworms) constitute a little known family of aquatic (both marine and freshwater) and terrestrial worms within the class Oligochaeta, phylum Annelida. They are less conspicuous in size than other soil Annelids like earthworms; their length varies in the range from 6 to 50 mm (Fig. 1). They are regarded as “mesofauna,” together with Acari and Collembola, as they occupy pore spaces with a diameter of less than 2 mm. As the rest of Oligochaetes, enchytraeids are hermaphroditic with amphimictic reproduction, although there are some species that can reproduce parthenogenetically and asexually by fragmentation and also by self-fertilization.

IDENTIFICATION

The lack of taxonomic information about enchytraeids is because of their small size and the confusing identification criteria. Only after the revisions published by Nielsen and Christensen^[1–3] is it possible to resolve the taxonomy of this group by providing a standard set of criteria for identification of genera and species. More than 600 species have been recognized, although the list is increasing.

Taxonomical criteria include external characteristics such as color (although the majority of the species are gray or whitish and usually gut contents, lymphocytes, chloragogen cells, and blood vessels are responsible for other colorations), size, number of segments, cutaneous glands (size, shape, and arrangement), setae (shape and arrangement) or setae follicles (except in the genus *Achaeta* where they are absent), dorsal pores (presence and position) and clitellum (position), and internal ones such as the number and location of oesophageal appendages, salivary glands, and septal glands, the origin of the dorsal vessel and the color of the blood, the shape of the

nephridia, and other characteristics of several reproductive organs (e.g., size and shape of seminal vesicles, length and shape of the sperm funnel, size and shape of the spermatheca, or the number of eggs). The analysis of these features requires a careful study of living, mature specimens because fixative liquids turn the tegument opaque, making it impossible to see the internal organs. Dózsa-Farkas^[4] provided a list of 20 characteristics necessary for the identification and description of enchytraeids; this emphasizes the difficulty of assigning specimens to the species level with certainty.

Furthermore, identification solely based on morphological aspects is problematic because of the high variability of these external and internal characteristics, the close similarity of related species, and the difficulty in identifying immature specimens.^[5] Therefore, the combined use of morphological and modern tools including spermatozoal ultrastructure, chemical composition of lipids, protein analysis and isoenzymes, immunological methods, and restriction fragmentation patterns is recommended.^[5,6]

SAMPLING

Sampling of field populations of enchytraeids is performed by taking soil cores of 5–6 cm diameter, which gives an area of 20 cm² for accurate counting of the worms and easy calculation of the numbers per square meter. The depth of the core depends on the soil type; because enchytraeids are mainly concentrated in the surface organic horizons, sampling depth has to be determined from the preliminary trials in the studied area. In relation to the number of sampled cores, O'Connor^[7] established that a minimum number of 10 units would ensure a representative estimate of the population numbers in a given ecosystem. The extraction of enchytraeids from the soil cores is based on the movement of the worms in response to a

Fig. 1 SEM of *C. sphagnetorum*: (A) whole worm and (B) ventral view of the head region showing the prostomium, the mouth, and the setae follicles.

gradient of light and temperature. Although several methods can be employed, the most widely used is “wet extraction” (Fig. 2), which has been shown to extract more than 95% of the total population of organic soils in three hours.^[8] A modified wet extractor has been proposed^[9] in which heating is omitted and the length of the extraction time is increased to several days. This method proved to be the best in terms of efficiency, but the extremely long extraction time could be inconvenient when processing a large set of samples. Further, a less laborious and faster method has been developed,^[10] which involves flooding the soil sample with Ludox (colloidal silica), followed by gentle mixing and finally counting the animals when they float to the surface of the solution. However, this method seems to be more efficient for recovering enchytraeids from defaunated soils.

SPATIAL DISTRIBUTION AND POPULATION DYNAMICS

Terrestrial enchytraeids are distributed globally, although the majority of the studies on their distribution have been carried out in Europe. Climatic events, competition

with other species, linkage with certain vegetation or soil types, and historical events are thought to be the main controlling factors of enchytraeid distribution.^[11]

Knowledge of the distribution of enchytraeids is highly variable because most studies are based on a low number of samples from few localities, and that these samples are taken over a short period of time with different core sizes, sampling depths, and extraction methods. For these reasons, it is very difficult to give accurate estimates of enchytraeid population sizes in different habitats. This results in the observed variability of abundance, with the numbers ranging from 0 to an average of 350,000 individuals per square meter. Didden^[12] reviewed the available literature and concluded that highest population densities are found in cold to temperate moist habitats, such as moorland soils, coniferous forests, and grasslands; however, low numbers have been recorded in these habitats when other soil characteristics are unsuitable (e.g., soil type).

Besides the methods employed to obtain the mean density values of enchytraeids in various habitats, seasonal climatic fluctuations play an important role in controlling the population dynamics. Temperature and/or moisture content, as well as other biotic activities, seems to be the main factors responsible for the observed variation in enchytraeid population sizes. Summer droughts can drastically affect total numbers as these organisms cannot survive if the soil moisture content is less than 10% of field capacity, and their reproduction rate can be reduced at water contents of 15%.^[13] Severe cold winters can also profoundly affect reproduction with frequent frost periods, leading to higher enchytraeid mortality.

Briones et al.^[14] carried out a transplant experiment to determine whether the responses to climate were species dependent or whether the community as a whole was responding to changes in environmental conditions. The data suggested that temperature was the main controlling factor determining population sizes and that response was species specific: some species were positively influenced by the warmer temperatures and responded by increasing their reproduction rate (*Cognettia sphagnetorum*), while other species were resistant to higher temperature (*Achaeta eiseni*) and/or dramatically reduced in numbers as result of the higher temperature regimes (*Cernosvitiella atrata*). Differences in reproduction strategies, including asexual reproduction by fragmentation by the former species (Fig. 3), and physiological adaptations such as a thicker cuticle in several species of the genus *Achaeta* could have conferred more resistance to the adverse conditions.

Enchytraeids mainly concentrate on the upper soil layers where organic matter is accumulated, although different species show varying vertical distributions. It is also known that some enchytraeid species can also migrate to deeper soil layers in response to moisture changes,^[14,15] but numbers in deeper layers depend greatly on other factors such as

Fig. 2 Wet extractor: the soil sample placed on 1 mm stainless metal mesh is submerged in a water-filled funnel. The temperature is gradually increased to a maximum of 40°C; after three hours, the worms are collected alive in the test tube.

Fig. 3 SEM of a tail fragment of *C. sphagnetorum* regenerating its head: (A) early stage and (B) later stage.

stage of decomposition and differences in food supply.^[16] Vertical migration seems to be the short-term strategy to overcome adverse temporal climatic conditions,^[14,15] at least for some species, whereas others are unable to burrow deeper.^[14]

FEEDING BEHAVIOR

Culture methods suggested that enchytraeids are fungivorous rather than bacteriovorous^[17] and ultrastructural studies of the intestinal content of several species of enchytraeids show that they are saprovores consuming plant debris.^[18] Moreover, some studies suggest that enchytraeids ingest mineral particles, fungi, bacteria, oats and yeasts, algae, and even dead bodies of lumbricids and arthropods. However, evidence suggests that microbivory has been underestimated,^[12] and microorganisms, and especially fungal mycelia, are important food sources for enchytraeid worms.^[19,20] Furthermore, studies using ¹⁴C carbon dating have shown that enchytraeids are also assimilating organic matter that consists predominantly of material that is on average 5–10 years old.^[21]

ECOLOGICAL IMPORTANCE

The contribution of the enchytraeids to energy and nutrient fluxes in soil ecosystems is the result of their consumption and assimilation efficiency, their influence on

soil properties, and feedbacks to other trophic levels.^[12] This contribution is difficult to assess because it depends on their activity in relation to other decomposer invertebrates and microorganisms, and on the amount and quality of the organic matter available. The assimilation efficiency of enchytraeid populations is very low; as a result, they have to ingest large quantities of organic material, and considerable amounts of undigested material are produced, creating a perfect substrate for microbial growth. The high production of fecal pellets, which later fuse to form a soil matrix, and the tunneling and burrowing activities are key influences of enchytraeids on soil structure^[22] and the morphological characteristics of organic horizons.^[23]

The feeding activities of enchytraeids also have strong effects on soil microflora. Hedlund and Augustsson^[24] demonstrated that the grazing activities of *C. sphagnetorum* increased the hyphal length and respiration of the fungus *Mortierella isabellina* and this could have important implications for organic matter turnover. Similarly, Cole et al.^[25] showed that enchytraeids enhanced microbial activity by 35% in the surface horizon of blanket peat.

The contribution of enchytraeids to total soil respiration is generally between 2% and 40%.^[12,26] However, warmer temperature regimes (e.g., a 5°C increase above the mean ambient temperature) induce biomass increases of their populations that could result in a near twofold increase in soil carbon dioxide release.^[27]

Enchytraeidae can also influence strongly the immobilization or excretion of certain cations, such as Ca²⁺.^[28] In addition, leaching of nutrients, particularly of N and P,^[29–31] is also enhanced by the presence of these organisms, but only when these nutrients are not limited.^[25,30] Studies have also demonstrated the effect of these organisms on carbon mineralization measured as dissolved organic carbon (DOC) released into soil solution.^[20,25,32] The positive effect of enchytraeids on the release of DOC is thought to be controlled by the effect of climate on their total abundance and vertical distribution.^[32]

Despite all the information that is available, the functional role of enchytraeids in terrestrial ecosystems has not been fully described. It is clear that in organic soils they are key organisms in terms of their effect on carbon and nitrogen dynamics. However, unlike with other soil fauna groups such as earthworms^[33] and nematodes,^[34] there is not a functional classification of enchytraeids (functional group = a grouping of organisms which affect a process in a similar way) with respect to the different functional roles of enchytraeid species in ecosystems. An attempt at an ecological classification of these organisms has been performed by Graefe and Schmelz^[35] in which species are classified in relation to pH, soil moisture, salinity, reproductive strategy, stress tolerance, and their occurrence in the gradient of humus forms.

CONCLUSION

Enchytraeid worms constitute a little known group of soil mesofauna because of their small size and the difficulties associated to their identification. They are commonly the most abundant invertebrates in high organic soils and frequently comprise over 70% of the soil faunal biomass. Their populations usually concentrate in the upper soil layers where they feed on a mixture of dead organic matter and microorganisms. They are known to be ecosystem architects that increase soil aeration by burrowing and have important effects on nutrient cycling. However, more information is needed to fully understand their functional role in terrestrial ecosystems as changes in environmental conditions can alter their population densities and their vertical distribution with important consequences for organic matter turnover.

Entisols

Larry T. West

National Soil Survey Center, U.S. Department of Agriculture—Natural Resources Conservation Service (USDA-NRCS) (Retired), Fayetteville, Arkansas, U.S.A.

Abstract

Entisols are soils with minimal pedogenic development and no diagnostic horizons other than an ochric epipedon. Entisols are the most abundant soil order comprising about 18% of the earth's land area. Because these soils are little affected by pedogenesis, their properties mostly reflect those of their parent material which vary widely. Most Entisols are on unstable geomorphic surfaces such as floodplains of rivers and streams, sand dunes, steep mountains, and mined or otherwise disturbed lands where erosion or deposition rate exceeds the rate of pedogenesis. The five Entisols suborders are (1) Aquepts—wet Entisols; (2) Fluvents—Entisols on stream floodplains; (3) Psamments—sandy Entisols; (4) Orthents—Entisols on steep slopes, in deserts, and/or that have resulted from soil disturbance; and (5) Wassepts—subaqueous Entisols. Entisols often have properties that limit their use, including flooding, steep slopes, sandy textures, poor drainage, and stoniness. Entisols have been and continue to be closely associated with human activities, however. Those on river floodplains are often agriculturally productive. In arid areas and mountainous areas, they provide watershed protection, recreation, and wildlife habitat. Many cities and towns on coasts or near rivers are built on Entisols, and the soil disturbance from urban development is continually creating Entisols. The environments in which many Entisols occur, such as floodplains, mountains, and deserts, make them easy to degrade. Thus, proper management is critical to preserve this component of the soil resource for the future.

INTRODUCTION

Entisols are soils that have minimal pedogenic development and no diagnostic horizons other than an ochric epipedon. Most Entisols occur on unstable geomorphic surfaces that are subject to frequent deposition, high rates of geologic erosion and truncation, or drastic disturbance by humans. Common Entisol landscapes include floodplains of rivers and streams, sand dunes, steep mountains, and mined or otherwise disturbed lands. Entisols may also be found on older, more stable landscapes if parent material or other factors retard pedogenesis. Because of limited pedogenesis, subsoil characteristics are typically those of the parent material.

Because of flooding, steep slopes, arid conditions, and other environmental factors, Entisols often have use limitations and can be easily degraded. Even so, Entisols have been and continue to be important for food production and other human activities. Entisols along river floodplains are often intensively farmed and are some of the most agriculturally productive soils in the world. Many towns and cities are located where rivers or oceans provide transportation, and these landscapes have abundant Entisols. In addition, human land disturbance from mining, intensive agricultural use, and in and near urban centers have created Entisols from the predisturbance soil resource.

SUBORDERS

Entisols are the most extensive soil order comprising about 18% of the earth's ice-free land area. About 60% of the Entisols occur in desert regions,^[1] and the largest area of Entisols occurs in Africa where they comprise about 27% of the continent's land area (Table 1). Entisols are divided into five suborders: Aquepts, Fluvents, Psamments, Orthents, and Wassepts.^[3]

Aquepts, the wet Entisols, are not extensive worldwide covering less than 0.1% of the ice-free land surface (Table 1). However, they are widely distributed in landscape segments that accumulate water and receive sediment additions, including salt marshes of coastal tidal zones, freshwater marshes and swamps, floodplain backswamps, and outwash plains. Except for seasonal saturation with water and reducing (anoxic) conditions at or near the surface, Aquept subsoil physical and chemical properties are widely variable and depend on properties of the parent material. Redoximorphic features resulting from reduction and oxidation of iron (Fe) and manganese are common in upper horizons. Aquepts in coastal marshes may contain sulfide minerals (Sulfaquepts) and/or have low bearing capacity (Hydraquepts). Aquepts seasonally saturated at or above the soil surface for long periods may accumulate sufficient organic matter to develop O horizons. Soils with O horizons thicker than 20 cm (histic epipedon), however,

Table 1 Land area of Entisols suborders by continent.

Suborder	North America	South America	Europe	Africa	Asia	Australia/Oceania	Global
Aquepts	— ^a	1	—	43	65	—	109
Fluvents	123	620	343	666	1,284	9	3,056
Orthents	1,121	631	299	7,896	4,634	761	15,834
Psamments	—	787	22	2,271	122	1,251	4,447
Wassents	—	—	—	—	—	—	—
Total	1,243	2,536	664	10,876	6,105	2,022	23,446
Total ice-free land area	21,671	17,681	9,599	29,778	43,924	8,000	130,681

^aThe suborder occurs on all continents but individual areas are too small to show and be tallied from global scale inventories.

are excluded from Entisols unless sulfidic materials are present within 50 cm of the surface (Sulfaquepts).^[4]

Fluvents are Entisols formed in recentwater-deposited sediments and are commonly found on floodplains, fans, and deltas of rivers and streams where the sediment deposition rate exceeds the rate of pedogenesis. About 2.3% of soils worldwide are Fluvents (Table 1). Fluvents are defined as having an irregular decrease in organic carbon (C) with depth or as having more than 0.2% organic C at a depth of 1.25 m.^[4] Because clayey and loamy strata commonly have more organic C than sandy strata, organic C decreases irregularly in stratified sediments. If the sediment has uniform texture, organic C content in lower subsoil horizons of Fluvents is more than 0.2% because of limited time for organic C decomposition. Physical and chemical properties of Fluvents are variable and depend largely on the source of the alluvial sediment, primarily material eroded from soil upslope in the watershed, serving as parent material. Fluvents landscapes are commonly subject to frequent flooding, which limits their suitability for many uses. Many Fluvents are fertile and productive, however, and are used extensively for crop production if flood cycles do not coincide with cropping periods.

Orthents are primarily the Entisols on recent erosional surfaces. The erosion may have been geologic or human induced by cultivation, mining, or other soil disturbing activities. Orthents are common in deserts and mountainous areas. They are the most extensive Entisols suborder and comprise about 12.1% of the earth's land surface (Table 1). Pedogenesis is limited in deserts because of the lack of water to drive pedogenic processes. In mountainous landscapes, erosion rates are high, and the rate at which weathered material is removed exceeds the rate of pedogenesis. In colluvial landscapes at the base of steep slopes, the rate of sediment deposition may exceed the soil development rate, which will also promote the occurrence of Orthents. Soils that have been formed or drastically disturbed by mining, road building, and agricultural activities such as deep subsoiling, urban/suburban development, and other human activities also classify as Orthents. Extremely slow weathering of resistant parent materials such as quartzite-rich bedrock retards horizon formation and results in

landscapes dominated by Orthents.^[5] Physical and chemical properties of Orthents are inherited from the parent material and vary as widely as the properties of the unconsolidated sediments in which the soils occur.

Psamments are the Entisols with sandy parent materials and cover about 3.4% of the earth's surface (Table 1). Specifically, Psamments must have texture of loamy fine sand or coarser throughout the control section (25–100 cm for soils deep to rock), and many Psamments have sandy textures to depths of 2 m or more.^[5] Common Psamment landscapes include sand dunes, natural levees, sand sheets, and sandy outwash plains. These landscapes can be young or ancient. On ancient landscapes, the materials in which Psamments occur are commonly quartzitic sands that do not readily form horizons because of resistance to weathering. Psamments are by definition sandy and thus are commonly low in plant nutrients and water-holding capacity and high in hydraulic conductivity. These characteristics limit crop production without irrigation and may impose limitations for other uses. Psamments are subject to wind erosion if bare, but with irrigation and proper management are often used for citrus, melon, and vegetable production.

Wassents are subaqueous Entisols formed in shallow water environments. These soils are permanently flooded and must have a positive water pressure at the soil surface for at least 21 hours of each day in all years.^[4] Depth of water overlying the Wassents surface must be such that rooted plants will grow, and this depth is generally considered to be about 2.5 m. Although they have been recognized as soils, Wassents and Wassists (subaqueous Histosols) have horizons that have formed as a result of the same generalized processes as subaerial soils—additions, losses, transfers, and transformations.^[6] Wassents occur in both salt and freshwater environments, and parent materials are commonly Holocene sediments. Physical and chemical properties of soils in this suborder vary widely and reflect the properties of the parent material, landform on which they occur, rate at which parent sediments were deposited, and chemistry of the aquatic environment.^[7] Properties and distribution of Wassents are important aids for design and management of systems for coastal and marine ecosystem management, conservation, and enhancement.^[7]

GENESIS

Although the state factor equation for soil formation,

$$S = f(Cl, PM, R, B, T) \quad (1)$$

where S = soil, Cl = climate, PM = parent material, R = relief, B = the biotic factor, and T = time,^[8] has many shortcomings, it is a convenient way to discuss the influence of various environmental factors on the genesis of soils, including Entisols. Limited time for soil development because of unstable landscapes is the most common and most easily understood reason for occurrence of Entisols. Entisols may occur, however, on relatively stable landscapes on parent materials that have been in place for a relatively long time. Conditions that lead to the occurrence of Entisols on more stable landscapes include arid climates that limit water movement through the soil, parent materials resistant to weathering, parent materials toxic to plant growth, and permanent or almost permanent, saturation with water.

Climate

Entisols occur in all climates, and there are no climatic restrictions on Entisol classification. Because low rainfall limits rates of leaching and other pedogenic processes, formation of diagnostic horizons, and evolution of Entisols to other orders is slower in arid climates than in semiarid and humid areas.^[5] In humid climates, mollic epipedons and Mollisols have been reported to form in as little as 100 years,^[9] and cambic horizons and Inceptisols may develop within 500–600 years or less.^[10,11] To form cambic or calcic horizons and Aridisols in arid environments, however, may take more than 1000 and possibly as much as 4000 years. Retardation of soil development by limited leaching partially explains the high proportion of Entisols that occur in arid regions. In addition, sparse vegetation and intense rainfall events enhance erosion and fluvial deposition, which limits soil development and contributes to occurrence of Entisols in desert areas.^[12,13]

Parent Material

Entisols are found on all types and compositions of parent material. Entisols are often associated with alluvial parent materials because many of these soils are found in floodplains with active fluvial deposition. Extremely resistant bedrock weathers slowly, which tends to maintain Entisol landscapes. Sediments dominated by resistant minerals, such as quartzitic sand, do not have or produce clay, Fe, or other mobile components needed to form diagnostic horizons that would result in the evolution of Entisols to other orders.^[14]

Relief

Entisols are often associated with two differing types of relief: steep eroding landscapes and nearly level to gently

sloping depositional landscapes. On steep convex slopes, erosion may result in soils that are rapidly truncated, which destroys diagnostic horizons that may be forming. On low-relief depositional areas, such as stream floodplains, deltas, fans, and colluvial footslopes, the rate of deposition may be such that the soil accretes faster than diagnostic horizons are formed. Entisols also occur in areas where the local relief results in soils that are permanently saturated, such as coastal marshes, freshwater swamps, and subaqueous environments. Permanent saturation inhibits leaching, translocation, and reduction–oxidation cycles that form diagnostic horizons.

Biota

Entisols can be found associated with any type of vegetation. Thus, little can be said about vegetation effects on genesis of Entisols. If humans are included, however, biota may have a profound impact on development and properties of Entisols. earth moving activities and/or deep tillage often destroys existing soils and creates Entisols.

Time

Time or age of the soil, specifically limited time over which soil development processes have proceeded, is the environmental factor most often associated with Entisol landscapes. If the landscape is “young” because of continual erosion or deposition, time for soil development will be limited, and Entisols will dominate. If parent materials are inert, however, Entisols may occur in old landscapes if weathering does not produce mobile components that are necessary for formation of diagnostic horizons.

CONCLUSIONS

Entisols are soils that are minimally developed and lack diagnostic horizons other than an ochric epipedon. Thus, properties of Entisols are those of the parent material and vary as widely as the properties of the materials in which they occur. Most Entisols occur on unstable geomorphic surfaces that are subject to frequent deposition, high rates of geologic erosion and truncation, or drastic disturbance by humans, although Entisols may occur in old stable landscapes if environmental or parent material characteristics retard pedogenesis.

Although Entisols often have properties that limit their use, they are intimately linked with human activities. Entisols on river floodplains are often highly productive and thus are used extensively for agricultural production. In mountainous and arid areas, Entisols are important for watershed protection, recreation, and wildlife habitat. Soil disturbance in contemporary urban landscapes as well as mining and other soil disturbing activities is continually creating Entisols. The environments in which many

Entisols occur, such as floodplains, mountains, and deserts, make them easy to degrade. Thus, proper management is critical to preserve this component of the soil resource for the future.

Environmentally Friendly Indigenous Technologies

Selim Kapur

Departments of Soil Science, Landscape Architecture, and Agricultural Engineering, University of Cukurova, Adana, Turkey

Erhan Akça

Center of Remote Sensing, Adiyaman University, Adiyaman, Turkey

Abstract

Indigenous technical knowledge (ITK) is quite known to be the critical factor for sustainable development. Empowerment of local communities is a prerequisite for the integration of ITK into the development process as well as the conservation and improvement of biodiversity. Basic economic factors such as efficiency, effectiveness, and sustainable development have been enhanced by appropriate ITK systems integrated into many development programs.

INTRODUCTION

Indigenous technical knowledge (ITK), as any other knowledge, calls for the consistent use, challenge, and adoption of the ever-evolving local contexts and support networks of traditional practitioners and communities.^[1] These help disseminate useful ITK to participatory actions within the development process with innovative mechanism incorporated at substantial magnitude.^[2]

ITK AND SUSTAINABLE LAND MANAGEMENT (SLM)

The primary reason for the ancient misuse of land that was sustainable and environmentally friendly at the beginning, as was the case with the Tikal situation, the Mayan site in Guatemala, and later gradually converted to a degradation process, has been due to the increase in population. Thus, the pressure of the number of underfed versus overfed people seeking higher standards of living has increased. This leads to the intensive and extensive use of limited land resources with the ultimate disaster of soil degradation. The misuse of the coastal environments of the Mediterranean encountered a similar fate of degradation due to the intense overgrazing and deforestation dating back to the period of King Solomon (ca. 3000 years B.P.) who supplied 80,000 lumberjacks to work in the Levantine forests with 70,000 more to skid the logs to the sea from a forest that is estimated to have been about 5000 km². The mountain ranges of ancient Lebanon during Phoenician times were covered with the famous cedar forests which were frequently transported to Egypt by ships laden with timber before 2900 B.C. as deciphered at an inscription at Karnak.^[3]

The degradation of the environment which mainly started by overgrazing since the Greek period and even earlier by deforestation created a new shrub ecosystem of maquis that is typical of the Mediterranean coastal and epicoastal areas. The beginning of the Eastern Mediterranean coastal settlements of Late Rome and Byzantine Empire (ca. 2000 B.P.) was also the cause of the subtle degradation process, which went on for ca. 4000 to 3000 years (Fig. 1). However, despite all the abovementioned degradation processes together with the mass migrations of people due to warfare, a well-established and consistent Mediterranean ecosystem evolved via an appropriate SLM. This system was followed throughout the mid-late Roman and Byzantine periods and was practiced in Southern Europe, North Africa, and the Middle East.^[3] The remaining forests during Roman and Byzantine periods were protected by strong legislations, as evidenced by the inscriptions in many late Roman monuments such as the one demarcating the forest boundary of Emperor Hadrian Augustus in the Lebanese mountains.^[3] This legislation, with high regard to an environmentally friendly SLM system, was partially followed in the Mediterranean Basin during different imperial periods including the Ottomans. Unfortunately, the overexploitation of natural vegetation by the locals, earlier during the Umayyad and Ottoman periods, caused further degradation of the well-established shrub environment particularly in North Africa and the Greek islands and parts of the Levant.^[5]

THE ANCIENT RATIONAL SLM OF THE MEDITERRANEAN

Ancient SLM was attained within the Mediterranean coast of Anatolia especially in Kizkalesi (Korykos) and Ayas

Fig. 1 The shoreline changes of the Aydıncık (Kelenderis) delta (S. Turkey).

Source: From Bal, Kelling, et al.^[4]

(Elaiussa Sebaste) during the late Roman–Byzantine periods (Fig. 2). The historical name of the latter means Emperor Sebastian's olive grove on the olive ecosystem of the late Roman Empire. This conserved the soil, harvested the scarce water sources, and protected the forests as well as the shrub ecosystem (the shrub agroecosystem or the olive ecosystem as coined by Akça et al.^[6] comprising olives as the main tree crop with carobs, vines, and figs) of fodder plants and cash crops of the highlands together with nonindigenous citrus (the sacred tree crop of the ancient Israelites and the Kibbat of the Arabs) adapted to the lower parts of the coastal regions of Southeast Asia around 1300 B.C.^[7]

Polygonal stone-walled terraces 1–2 m high and 0.5–5 m wide (Fig. 2), similar to the ones in Lebanon, South France, and Tunisia, were constructed as part of the ancient ultrastructure in the area consisting of

Fig. 2 Korykos and Elaiussa Sebaste settlement pattern (A), ancient and present land use map of the Korykos area (B), and polygonal stone wall terraces (C).

Source: From Akça, Kelling, et al.^[6]

functional land strips (from several hundred meters to kilometers long). These strips were used for grazing by goats and sheep as barn or semidomesticated flocks. Widespread grazing of goats in the late Roman period in Southern Anatolia dating back to late antiquity is also documented by the use of two types of textiles, namely the linen and a coarse cloth made from goat hair giving rise to the ancient Greek name of the region, “Cilicia” (Cilicium in Latin^[8]). Seminomadic people (Yuruks) of the Cilician highlands (local yaylas) live in tents made from goat hair during summer grazing. Together with native olive orchards, semidomestication of grazing large land fragments/pastures has been practiced for a long time in the Turkish Aegean island of Gokceada (Imbros) and the Greek islands. The Lebanese (Beirut) stone-walled terraces of the Beiteddine mountain are estimated to have cost U.S.\$2000–5000/acre, assuming the cost of labor at 40 cents/hr. These immense structures show the extent of the people’s concern for protecting their soils on marginal and scarce lands of the Mediterranean Basin.^[3,6]

THE PLOW IMPLEMENT OF THE MILLENNIA

The weed management practices of the farmers in the Usambara mountains in Tanzania^[9] and the highly efficient Ethiopian plow, the “Maresha,” are the symbols of the ingenuity of African ITK. This plow includes animal-drawn drainage equipment, the broad bed maker, used along with improved crop varieties, fertilizers, and other agricultural practices. The broad bed maker is a modified traditional Ethiopian plow used for the construction of broad beds and furrows, allowing drainage of excess water during heavy rains. The Anatolian plow dating back to the pre-Hittites (ca. 4000 B.P.) was used for cultivating the indigenous wheat species of *Triticum monococcum* and *dicoccum*, with their crossbred varieties being cultivated using similar plows in marginal areas. These plows are used to till the soil to a depth of 10–15 cm with minimal soil disturbance (Fig. 3).^[10,11]

This implement has been extremely efficient especially in olive and pistachio groves. These groves are

traditionally located on calcrete (caliché) surfaces in Anatolia and the Middle East (especially the Levant) and date back to the birth of the olive tree.^[12,13] Thus, the proper tillage of the shallow soils causes the mixing of the stone fragments of the underlying soil-derived calcrete parent material, which contains sufficient amounts of palygorskite clay minerals forming a porous microstructural pattern with calcite minerals. These systems help retain plant-available water throughout the year in the ancient rainfed olive (the Mediterranean coast and epicoast) and pistachio (semiarid and mild-arid Southeast Anatolia and the Middle East) groves. The high terrace (TH, mudflow terraces of Late Pleistocene and Early Holocene) and low terrace (TL, Holocene river terraces) sequences of the indigenous olive, carob, and vineyard surfaces on geomorphological–pedological sections represent similar sites in the Mediterranean Basin (Fig. 4). Fig. 4 illustrates the layout of typical olive, carob, and vineyard sequences on limestone, mudflows, and lacustrine deposits with calcretes underlying the widespread fertile shallow soils (Alfisols; ca. 30 cm) of South and Southeast Anatolia as well as the sustainably cultivated lands of Southern Europe and North Africa by the ancient Greeks and Romans.^[14]

APPLICATIONS OF ITK TO SLM

The momentum for developing a philosophical concept for improving particular technologies on land management was gained by ITK in India. A proper example of this is the ITK on the use of shifting sand dunes—the theri soil, which has been passed from one generation to the next. The theri soil—formed by wind erosion—and widely distributed in Tamil Nadu (the coastal belt of the Bay of Bengal) is red to dark red in color, sandy, single-grained, and neutral.^[15] A study conducted in Sivapur in 1993 revealed the use of drought-resistant indigenous crops of palmyra (*Borassus flabellifer*), odai (*Acacia planifrons*), tamarind (*Tamarindus indica*), and neem (*Azadirachta indica*), which are highly suitable for the theri ecosystem but less profitable with irrigation. Farmers have been growing rice, groundnuts, coconuts, and bananas as well as cashew and other indigenous species when no irrigation is available. Farmers have been reclaiming these sandy soils by the addition of tank silt (ca. 100 tons/ha) with the use of farmyard manure and regionally developed irrigation systems based on ITK. The experiences of Sivapur village demonstrate that when farmers of India, as elsewhere in the world, are under pressure, they will develop new techniques for cultivation based on ITK.^[16] Similar technologies have been developed in the Indian subcontinent based on ITK in Nepal for fodder tree management for livestock.^[17] ITK has a proven scientific validity for growth and survivability of the seedlings as well as foliage production from Bedulo (*Ficus clavata*),

Fig. 3 Anatolian plow with rural family of late 19th century. **Source:** Drawing Courtesy of A. Başçetinçelik, University of Çukurova, Turkey.

Fig. 4 Pedological section (A) of TH (B) and TL (C) surfaces.

Source: From Kapur, Cavusgil, et al.^[18]

Ginderi (*Premna integrifolia*), Khanayo (*Ficus semicordata*), Kabro (*Ficus lacor*), and Pakhuri (*Ficus glaberrima*).

The ultimate level of ITK based on the participatory approach by farmers in the Indian subcontinent is the “Vertisol Technology.” This technology was developed to manage problematic soils (e.g., those that develop wide cracks in dry periods) with specially developed agronomic practices. These practices not only increase the production but also reduce erosion during the periods of heavy rains. The International Crops Research Institute for the Semi-Arid Tropics’ (ICRISAT’s) conceptual approach on implementation of soil technologies has been used in Africa and elsewhere in Asia, namely for chickpea production in Kenya and Uganda. The ITK used included replacement of traditional pigeon pea varieties by improved cultivars and utilization of the available indigenous system. Pest control was achieved by boiling local plants, weeds, or tree components (leaves, roots, and bark) in water. The mixture is sprayed in the fields to avoid pest infestations. The efficiency of these traditional systems has yet to be surpassed and serves as viable alternatives to costly chemicals. Moreover, the indigenous pest control does not lead to pest resistance as in the case with chemicals.^[17]

Finally, identifying problems and creating solutions in SLM, for small-scale farmers within the concept of

indigenous agroecological zones, may help define research agendas for international and national agricultural research centers that seek to alleviate poverty, as in the case of ICRISAT’s ITK studies.^[17]

Enzymes

Veronica Acosta-Martinez

Cropping Systems Research Laboratory, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Lubbock, Texas, U.S.A.

Susanne Klose

University of California—Davis, Davis, California, U.S.A.

Abstract

The functionality and resilience of natural and managed ecosystems mainly rely on the metabolic abilities of microbial communities, which are the main sources of enzymes in soils. Enzyme-mediated reactions are critical in the decomposition of organic matter, cycling of nutrients, and in the breakdown of herbicides and pollutants. This entry describes the groups, locations, and role of enzymes in soils and the relationship between soil enzyme activities, namely, soil properties, soil management, and pollution.

INTRODUCTION

Enzymes are protein catalysts in biochemical reactions and an integral part in nutrient cycling and energy transformation in soil. Enzymes (E) catalyze reactions without undergoing permanent alteration by reducing the activation energy via the formation of an enzyme–substrate complex (ES); thus, the product (P) of the reaction is released at faster rates than if the enzymes were not present.

Plants, animals, and microorganisms are sources of enzymes in soils, but the microbial component, composed of protozoa, fungi, actinomycetes, and bacteria, is their main source.^[1] Despite the short life cycle of microorganisms, most enzymes contribute to the degradation potential of soil: 1) intracellularly inside an active cell and 2) extracellularly in the soil solution or attached to soil surfaces. Enzyme-mediated reactions are essential in the decomposition of organic residues, humification, release of plant-available nutrients, transformation of nitrogen (N) compounds including N₂ fixation, nitrification, and denitrification, stabilization of soil structure, and degradation of xenobiotic (foreign or strange) compounds.

SOIL ENZYME CHARACTERISTICS

Grouping of Soil Enzymes

Enzymes are categorized according to the mechanism of the reaction they catalyze, and four major enzyme groups have been studied in soil:

1. Oxidoreductases catalyze the electron transfer from one molecule to another. Examples are catalases that participate in the oxygen release from hydrogen peroxide and dehydrogenases that catalyze organic matter oxidation. Dehydrogenases are strictly intracellular enzymes and thus reflect the total oxidative activities of the soil microflora.
2. Transferases are involved in transferring groups [i.e., one-carbon (C), glycosyl, hydroxymethyl, formyl, and carboxyl] from one molecule to another. Examples are dextran sucrose transferase that catalyzes the transfer of glucosyl residues from sucrose to dextran polymer releasing glucose and fructose, and thiosulfate S-transferase (rhodanese) that catalyzes the transfer of cyanide to thiosulfate releasing thiocyanate and sulfite, which is an intermediate step in elemental sulfur (S) oxidation.
3. Lyases are enzymes involved in the cleavage of chemical bonds other than that by hydrolysis or oxidation. Selected N-cycling enzymes belong to this group, such as: 1) glutamate decarboxylase, which is involved in the decarboxylation of glutamate; 2) tyrosine decarboxylase, which catalyzes the removal of the carboxyl group from tyrosine; and 3) L-histidine ammonia lyase, which catalyzes the deamination of L-histidine producing urocanate and ammonia.
4. Hydrolases catalyze the hydrolysis of various chemical bonds (i.e., ester, glucosyl, ether, and peptide bonds) by reacting with water. Most commonly assayed soil enzyme activities belong to this group, such as phosphatases, urease, L-asparaginase, cellulase, xylanase, β -glucosidase, protease, and arylsulfatase.

Location of Soil Enzymes

The total activity of any enzyme in soil is a composite of activities associated to 10 different locations^[2] (Fig. 1).

Fig. 1 Locations of enzymes in soil: (i) enzymes functioning within the cytoplasm of proliferating microbial, animal, and plant cells; (ii) enzymes restricted to the periplasmic space of proliferating gram-negative bacteria; (iii) enzymes attached to the outer surface of viable cells with active sites extending into the soil environment; (iv) enzymes released into the soil solution by living cells during cell growth and division; (v) enzymes within non-proliferating cells such as fungal spores, protozoa cysts, plant seeds, and bacteria endospores; (vi) enzymes attached to an entire dead cell and cell debris; (vii) enzymes leaking from intact cells or released from lysed cells, originally located on the cell membrane or within the cell, which may survive for a short period in the soil solution; (viii) enzymes temporarily associated with soluble or insoluble enzyme-substrate complexes; (ix) enzymes absorbed to the external or internal (i.e., within the lattices of 2:1 layer silicates) surfaces of clay minerals; and (x) enzymes complexed with humic colloids by absorption, entrapment, or copolymerization during humification.

Approaches to separate extracellular enzymatic activities from those associated with soil microorganisms have included exposure of soils to: 1) elevated temperatures; 2) fumigants; 3) plasmolytic and antiseptic agents; and 4) irradiation with gamma rays or electron beams. Research with several soil enzymes showed that chloroform fumigation of soil led to an increase in the activities of urease and aryl-sulfatase. This increase in enzyme activities was believed to be due to the release of intracellular microbial enzymes and thus may provide an estimate of the intracellular fraction of these enzymes in soil.^[3] All approaches are limited by the potential of enzyme denaturation by these treatments or degradation by proteases. Distinguishing the contribution of accumulated enzymes and enzymes of active microbial communities to total enzyme activities is as a challenge in soil enzyme research because of the importance of enzymatic reactions in various processes linked to soil metabolic functioning.

Enzyme Protein Concentrations in Soil

Enzyme protein concentrations (mg enzyme protein kg⁻¹ soil) can be calculated by comparing the activity of a

reference enzyme protein and the corresponding enzyme in soils, assuming that the chemical structure of the reference protein is similar to that of the soil enzyme.^[3] Enzyme protein concentrations range widely between 0.014 and 3.67 mg protein kg⁻¹ soil for glycosidases, between 0.73 and 3.38 mg protein kg⁻¹ soil for amidohydrolases, and between 2.1 and 22.5 mg protein kg⁻¹ soil for phosphatases in agricultural surface soils with varying pH values (5.5–7.9), organic C (12–44 g kg⁻¹), and clay content (170–360 g kg⁻¹).

ROLE OF SOIL ENZYMES (HYDROLASES) IN BIOGEOCHEMICAL CYCLING

C-Cycling (Glycosidases)

C occurs in soil in simple or complex organic and various inorganic forms (carbonates and CO₂), which undergo biochemical transformations involving enzyme reactions. Glycosidases play a key role in the breakdown of low-molecular-weight carbohydrates (i.e., disaccharides) producing sugars, which are important energy sources for soil microorganisms. Major soil glycosidases are as follows: 1)

Fig. 2 Enzymatic cellulose degradation.

α -glucosidase (maltase) catalyzing the hydrolysis of α -D-glucopyranosides (maltose); 2) α -galactosidase (melibiase) catalyzing the hydrolysis of α -D-galactopyranosides; 3) β -galactosidase (lactase) catalyzing the hydrolysis of β -D-galactopyranosides; and 4) β -glucosidase (gentibiase or cellobiase) catalyzing the hydrolysis of β -D-glucopyranosides (cellobiose). The β -glucosidase activity catalyzes the final step of cellulose degradation, which is the most abundant organic compound in the biosphere (Fig. 2).

N-Cycling (Amidohydrolases)

N is the most commonly limiting plant nutrient in soils because more than 95% of the total N occurs in organic forms, unavailable to plants. Amidohydrolases including L-asparaginase, L-aspartase, L-glutaminase, and amidase cleave C–N bonds other than peptide bonds in linear amides and release plant-available NH_3 . L-Asparaginase catalyzes the hydrolysis of L-asparagine to aspartate, which is further hydrolyzed by L-aspartase to fumarate:

Phosphorus (P) Cycling and S-Cycling (Phosphatases and Arylsulfatase)

P is present in soil in a variety of organic and inorganic forms. P is essential for plant development but is the least mobile of the major plant nutrients. Phosphatases are crucial in organic and inorganic P transformation processes and plant nutrition. Phosphatases belong to a broad group of enzymes catalyzing the hydrolysis of both esters and anhydrides of H_3PO_4 . Most common phosphatases studied in soils are phosphomonoesterases and phosphodiesterases.^[1] Phosphomonoesters are hydrolyzed by acid or alkaline phosphatases (phosphomonoesterases) depending on the soil pH:

S occurs in organic forms in most surface soils, and mineralization of these organic fractions is critical for

plant nutrition. Arylsulfatase is believed to be partially responsible for S-cycling in soils by catalyzing the hydrolysis of organic sulfate esters following the reaction:

ENZYME ACTIVITIES AS INDICATORS OF SOIL METABOLIC FUNCTIONING

Enzyme Activities and Soil Properties Relationship

Stabilization and protection of soil enzymes by humic and clay particles may increase the resistance of enzymes to changes in soil temperature and pH. Enzyme activities increase with increasing soil temperatures and are generally inactivated at temperatures between 60°C

Table 1 Enzyme activities (mg product kg⁻¹ soil h⁻¹) as affected by soil texture, organic C content, and soil management at 0–5 cm depth (Past = pasture; Rot = rotation; Mono = monoculture) as summarized from research conducted in semiarid soils.

Texture	Organic C (g kg ⁻¹)	Soil classification	C-cycling			C- and N-cycling			P-cycling			S-cycling		
			β-Glucosidase			β-Glucosaminidase			Alkaline phosphatase			Arylsulfatase		
			Past	Rot	Mono	Past	Rot	Mono	Past	Rot	Mono	Past	Rot	Mono
Clay	8.5–13.3	Torretic Paleustolls	240	185	125	58	35	18	305	329	150	40	38	23
Sandy clay loam	3.8–18.7	Aridic Paleustolls	198	63	31	34	8	4	308	119	38	58	23	11
Loam	4.9–13.1		186	89	60	58	34	30	149	27	31	18	5	2
Sandy loam	3.1–14.0	Aridic Paleustalfs	124	78	23	40	13	4	190	147	45	34	13	9
Loamy sand	2.8–4.0		49	46	22	9	7	5	120	46	28	25	9	2
Sand	1.4–1.8		49	66	15	9	7	2	63	46	15	24	19	3

Source: From Acosta-Martínez, Mikha, et al.^[4] and Acosta-Martínez, Klose, et al.^[5]

and 70°C. Each enzyme has a specific pH value at which the reaction rate is optimal, and at each side of this pH optimum the rate is lower. Phosphomonoesterases, e.g., are classified as acid and alkaline phosphatases because they show optimum activities in soils under acid and alkaline ranges, respectively. As presented in Table 1, enzyme activities are higher in clay and loam soils than in sandy soils following the clay and organic C contents.^[4,5] Enzyme activities generally decrease with increasing soil depth following the amounts of organic C and N along the soil profile and are higher in the rhizosphere when compared with the bulk soil.

Enzyme Activities and Soil Management Relationship

Crop rotation, fertilization, tillage, and soil amendment affect enzyme activities by altering soil structure, bulk density, soil pH, and amounts and distribution of organic matter and nutrients in soil. Soils under crop rotations generally show higher enzyme activities compared with monocropping systems owing to diversified organic inputs, improved soil structure, nearly year-round rhizosphere and plant cover, and higher root density. Changes in enzyme activities may even anticipate the changes in organic matter of soil as affected by soil management. However, the changes in enzyme activities due to crop rotations can depend on the soil type and the quantity and quality of plant residues and nutrients entering the soil. Inorganic fertilizer applications can affect enzyme activities through higher plant yields, crop residue amounts, and changes in soil pH and soil solution chemistry. However, the addition of enzyme reaction products by inorganic fertilizers can also suppress enzyme synthesis.^[6] Liming of agricultural soils can stimulate most enzyme activities because of increases in soil pH, except for acid phosphatase activity, which is decreased by increasing soil pH. Organic soil amendments can lead to an initial increase

in enzyme activities, but subsequent additions may fail to sustain high enzyme activities.^[7] Intensive tillage generally decreases enzyme activities in the upper 10 cm soil layer.^[8]

Enzyme Activities and Soil Pollutants Relationship

Organic contaminants, heavy metals, and pesticides are pollutants of major environmental concern because of their persistence and broad biocidal activity against key soil processes affecting ecosystem stability and resilience. Each soil enzyme reacts differently to soil pollution depending on the type of pollution, pollutant concentration, and soil type.^[9] Soil amendments with urban and industrial wastes, releasing various organic and inorganic pollutants, waste or high-salinity water, or atmospheric depositions may affect soil microorganisms and enzyme activities in various ways. For example, the addition of organic waste materials generally enhances soil enzyme activities owing to the increase in soil organic matter and nutrient contents, and improvement of soil physical properties unless these organic wastes also contain high levels of heavy metals and other toxic compounds. The degree of enzyme activity inhibition by organic wastes depends on the enzyme, soil organic matter, and clay contents, as well as the concentration and form of heavy metals in these waste materials. Heavy metals can react with active groups of enzymes resulting in inhibition or inactivation or decreasing enzyme proliferation by changing the microbial community.^[10] Pesticide effects on soil enzyme activities are difficult to summarize because pesticides are subjected to different microbial processes, including biodegradation, cometabolism, polymerization or conjugation, and accumulation in microorganisms.^[6] Short-term studies have reported a small initial stimulatory effect on dehydrogenase activity and slight increases or no significant effect on the activities of ureases and phosphatases when pesticides are applied at recommended field rates.^[6]

If pesticides are applied to soils at very high concentrations simulated by accidental spills, enzyme activities are significantly reduced.^[6] The toxicity of pesticides, in particular soil fumigants, is related to: 1) their interference with respiratory enzymes; 2) their ability to chelate metal cations; 3) inhibition by the unchelated ion; and 4) toxic degradation products.^[11] Soil fumigation with six different fumigant pesticides reduced the activities of arylsulfatase, dehydrogenase, acid phosphatase, and β -glucosidase between 6% and 62% over a three-month period. Fumigated agricultural soils showed longer-term decreases in the activities of β -glucosidase, acid phosphatase, and dehydrogenase. Changes in enzyme activities were fumigant specific and varied between different locations, supporting the hypothesis of a significant natural variability within and between soils, and the influence of the soil type on the response of enzyme activities to biocides and soil pollutants.

CONCLUSION

The information obtained from different enzyme activities should be interpreted with caution because enzymes are involved in very specific biochemical reactions, and the total enzyme activity measured in a soil is a reflection of the potential activity only. Despite the complexity in the behavior of biochemical reactions toward various pollutants and chemicals including fertilizers, enzyme activities are considered as a sensitive indicator of soil disturbance, environmental stress, and changes in soil metabolic functionality.

Erosion

Dennis C. Flanagan

*U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS),
West Lafayette, Indiana, U.S.A.*

Abstract

Erosion is the detachment of soil particles and transportation to another location. Wind erosion occurs when wind speed exceeds a critical threshold level, and loose soil particles or soil particles removed by abrasion then move in one of three ways: creep, saltation, and suspension. Erosion by water is typically by raindrops or by concentrated water flows on a soil surface. Raindrops vary in size from about 0.5 mm in diameter to 4 mm or larger and can reach terminal velocities of 10 m/s. The momentum of large drops at high speeds can result in soil compaction and ejection of water and sediment sprays (splash) at the point of impact. Water on a soil surface that does not infiltrate will flow downhill and typically coalesce into small channels or “rills.” When enough water is flowing in a rill, flow shear forces will act to detach soil from the channel bottom and sides. Rills are the major pathway for both water and sediment detached by raindrops and flow shear stress to move downslope and ultimately off of a piece of land. In larger channels, similar detachment due to flow shear forces can also occur that can produce different types of gullies, as well as additional soil loss from other processes including bank sidewall sluffing and headcutting. A number of practices are recommended to reduce or prevent erosion, including use of mulch or plant residues to protect the soil surface, terraces to reduce slope length and steepness, and grade control structures to safely transport water flow to lower elevations.

INTRODUCTION

Soil erosion is the detachment or breaking away of soil particles from a land surface by some erosive agent, most commonly water or wind, and subsequent transportation of the detached particles to another location. Usually, erosion occurs when a fluid (air or water) moves into and/or across a soil surface. Fluid and sediment particle impact forces, shear forces, and turbulence act to detach and lift soil into the fluid flow that then transports the particles away (Fig. 1). The force of gravity moves detached soil particles downward, while cohesive forces between soil particles resist detachment and transport. Physical and chemical dispersion can disrupt cohesion and break soil aggregates into smaller and more easily transported particles. At some time and location away from the initial point of detachment, the sediment particles will eventually move back down to a state of rest on a soil surface, in a process known as deposition or sedimentation.

Erosion is a natural process and is a critical factor in soil formation from rock parent material. However, once productive agricultural soils have been formed over periods of thousands or millions of years, the erosion of soil material is then usually very low or negligible because of the effects of protective natural plant and residue cover. Human activities are responsible for greatly accelerating erosion rates, usually by reducing or eliminating plant and residue cover. This exposes the soil to wind and water erosive forces,

weakening the soil cohesive forces by tillage disturbance and increasing the erosive agents, particularly by activities that increase surface runoff.

EROSION BY WIND

Erosion by wind occurs when wind speed exceeds a certain critical or threshold value. Soil particles can be detached and moved through suspension, saltation, or creep (Fig. 1). Suspension usually lifts the smallest soil particles (clays, silts, and organic matter) so high into the air mass that they are easily kept in motion and can travel for long distances. Soil particles that move by creep are larger sand grains and aggregates that stay in contact with the soil surface at almost all times—their motion is often through rolling and bouncing. Saltating soil particles are usually moderate in size and, once detached, move in trajectories up into the air and then back down to the soil surface. Saltating particles often cause further detachment through abrasion, by striking the soil surface with sufficient momentum to dislodge additional soil particles from the *in situ* soil mass.

EROSION BY WATER

The most common types of soil erosion by water are sheet and rill erosion on upland areas, channel and gully erosion in small watersheds, and stream channel and bank erosion

Fig. 1 Soil erosion by wind, showing the three modes of movement (creep, saltation, and suspension).

in larger catchments. Sheet erosion is caused by the action of raindrops (Fig. 2) and shallow overland flows that remove a relatively uniform depth (or sheet) of soil. Raindrops vary in size from about 0.5 mm in diameter to 4 mm or larger and can reach terminal velocities of 10 m/s. The momentum of large drops at high speeds can result in soil compaction and ejection of water and sediment sprays (splash) at the point of impact. Raindrop impacts on shallow surface water flows also keep sediments previously detached by splash in motion. Water on a soil surface that does not infiltrate will flow downhill and typically coalesce into small channels or “rills” (Fig. 3).

Because of the uniform nature of the soil loss, it is often difficult to detect and gauge the extent of damage caused by sheet erosion. On the contrary, rill erosion occurs in well-defined and visible flow concentrations (Fig. 3). Soil detachment in rills is largely because of flow shear stress forces acting on the wetted perimeter of the rill channel (Fig. 4). Once detached, larger sediment particles move as bedload, rolling and bouncing downslope with the flow, and are almost always in contact with the soil (or bed)

Fig. 2 Soil detachment by raindrop impact and shallow flow transport.

Fig. 3 Rill erosion, which is caused by the concentration of flowing water, forms easily recognizable regions of detachment on a soil surface.

surface. Smaller sediment particles (silts and clays) are much easier to transport and travel in the rill channels as suspended load. Rills are also the major pathways for transporting away sediment that is detached by sheet erosion (also known as interrill detachment).

By definition, rill channels are small enough to be obliterated by tillage and will not reform in exactly the same location. As one moves from smaller hillslopes to larger fields and watersheds, additional erosion processes come into play, because of the increasing amounts of runoff water. Gullies are incised erosion channels that are larger than rills and form in regions of large runoff flow concentration. Ephemeral gullies are a common type of erosion feature in many fields (Fig. 5). They are small enough to be tilled over but will re-form in the same location owing to the convergent topography in small catchments. Runoff flows from large events can erode down through tilled soil layers, until a non-erodible layer is reached; then, the ephemeral gully channel will widen, and soil detachment will decrease. Classical gullies are larger erosion features that cannot normally be tilled across (Fig. 6). The physical

Fig. 4 Soil detachment and transport in rills are largely because of flow shear forces.

Fig. 5 Typical ephemeral gully, located in a soybean field in Indiana.

processes in classical gullies include other factors such as headcutting, seepage, sidewall sluffing, and cleanout of fallen sidewall materials.

As the size of watersheds increases further and streams increase in size and become perennial (because of subsurface water flows from springs and aquifers), the erosion processes in play change as well. Stream and channel erosion at these larger scales can include scouring of the channel beds as well as sediment contributions from the channel banks. Areas in streams may be in states of degradation, in which active detachment is lowering the level of the channel bed, or they may be in states of aggradation, in which sediment deposition is raising the bed level.

GRAVITY-INDUCED EROSION

There are also less frequent but more extreme forms of gravity-induced erosion on steep slopes from saturated soils that can be exacerbated by events such as earthquakes. Large masses of land can slowly or rapidly slide down hills, when the cohesive forces holding them in place fail (land creep, landslide, debris flow, etc.). These types of erosion events typically occur when large rainfall or snowmelt water depths saturate soil profiles and weaken their resistance to slip. Human activities such as removal of

Fig. 6 Classical gullies in the Loess Plateau of China. Terrace farming is being used to stabilize some of the hillslopes.

deep-rooted trees by logging can increase the risks of occurrence of erosion events on susceptible hill slopes.

EROSION ASSESSMENT

Erosion is a serious problem within the United States and throughout the world. In 2007, the U.S. Department of Agriculture–Natural Resources Conservation Service estimated that about 1.7 billion tons of soils are lost each year from non-federal rural lands because of sheet and rill erosions by water and erosion by wind.^[1] Also, 28% of cropland in the United States is eroding at excessive rates. These estimates are on the low side because erosion of other types (e.g., gully) and at other locations (e.g., urban lands and federal lands) were not included in this inventory. Throughout the world, the Food and Agriculture Organization has estimated that 16% of the total land area (21,960,000 km² of 134,907,000 km²) is subject to significant risk of soil erosion.^[2] In Asia, South America, and Africa, soil erosion rates are highest at an estimated average of 30–40 t/ha/yr, while in Europe and North America, average rates are somewhat lower at about 17 tons/ha/yr.^[3,4] A sustainable rate of soil loss (rate of soil loss is equal to rate of soil formation) is thought to be about 1 t/ha/yr.

Erosion assessment can be a difficult task to perform in the field, and monitoring of soil lost and transported by wind or water can be expensive and prone to measurement errors. Gullies are easy to recognize, while soil lost to sheet and rill erosion is hard to gauge. Sheet and rill erosion may be occurring on hill slopes that are adjacent to a gully and may actually contribute more sediment to runoff water than the gully itself. Visual assessment of rates of wind erosion losses can be even more difficult to perform. Mathematical equations or sets of equations have been developed and used since the mid-1900s to estimate the rates of soil loss caused by wind (“Wind Erosion Equation”^[5]) or water (“Universal Soil Loss Equation”^[6,7]). More recently, computer models are being applied to simulate soil erosion processes and to estimate detachment, transport, and deposition of sediment.^[8,9]

EROSION IMPACTS

Erosion has a range of impacts, both on-site and off-site. Soil loss removes fertile topsoil, organic matter, and nutrients, thus decreasing the tilth, water-holding capacity, and general productivity of a soil for on-site agricultural production. Regions of detachment can expand to dislodge and remove small crop seedlings, while regions of deposition can bury and kill small plants. In the case of wind erosion, the erosion process can damage fragile young seedlings through abrasion of plant tissue. When excessive detachment occurs, such as is the case with gully erosion, whole sections of fields may be destroyed or may become inaccessible to farmers and their equipment. Eroded sediment

can cause a number of off-site problems, including deposition along windbreaks, ditches, and waterways. The deposited sediment may require costly dredging and removal operations. Nutrients and pesticides associated with sediments can also contaminate air and water bodies. Erosion by wind can cause massive dust storms that blind drivers and cause highway accidents, and sand particles can abrade and damage painted surfaces on buildings and vehicles. Some estimates are that the cost of combined on-site and off-site effects from soil erosion in the United States is as high as \$44 billion (1992 dollars) per year.^[3]

EROSION CONTROL AND SOIL CONSERVATION

Many nations have created government agencies or organizations to specifically deal with soil erosion problems and to interact with landowners to get conservation practices implemented on the landscape. In the United States, the Natural Resources Conservation Service assists in the implementation of soil conservation practices on agricultural lands, the Forest Service manages sediment delivery from forests and timber harvest roads, and the Bureau of Land Management manages soil loss on range and grazing lands. The Department of Defense is responsible for managing erosion and off-site sediment delivery from lands that it uses for military training activities. However, in some countries, efforts to address and minimize erosion problems are non-existent or severely limited because of poor economic conditions, failure to recognize the erosion threat and/or the extreme magnitude of the soil erosion.

A variety of soil conservation methods is available that can be applied on a landscape to minimize erosion problems caused by wind or water. Wind erosion can be controlled through the use of windbreaks, crop residues, and tillage to induce significant surface roughness. Control procedures for erosion by water need to be determined based on the types of active erosion processes. For example, if sheet and rill erosion are a major problem, then some type of conservation tillage practice that leaves large amounts of crop residues intact on the soil surface may be appropriate. However, if the water erosion problem is because of large amounts of surface runoff water concentrating in a field and forming an ephemeral gully, then crop residues may not be adequate; instead, permanent vegetative cover in a grass waterway may be necessary, along with appropriate engineering structures (e.g., drop box and terraces). Erosion prediction models can be used to assist in selecting and designing appropriate conservation practices.

Through the use of proper conservation planning and application of appropriate soil conservation methods, most erosion problems can be minimized or eliminated. This is critically important if the soil resource is to be preserved for continuous use in food and fiber production for current and future generations.

CONCLUSION

Erosion is a natural process of soil detachment and removal that can be greatly influenced through human activities (agriculture, construction, timber-harvesting, etc.). Use of proper erosion prediction technology and appropriate erosion control methodologies is critical if we are to sustain the soil resource for use by future generations.

B. Krishna Rao

Research Center, Indian Institute of Soil and Water Conservation, Vasad, India

Abstract

Soil erosion is one of the major constraints to sustainable food production in hilly ecosystems. The magnitude gets amplified with improper agricultural management practices and poor adoption of soil conservation practices. The entry describes major biological and mechanical erosion control measures and their suitability. The major biological erosion control measures are contour cultivation, cover cropping, vegetative filter strips, hedge row barriers and selection of appropriate cropping systems having good canopy cover and erosion resistance crops. The mechanical measures normally adopted in the arable sloping lands are contour bunding, graded bunding and terracing. In non-arable lands, drainage line treatments or gully control structures are used, which may be temporary or permanent in nature. Drop spillway, drop inlet spillway and chute spillway are the common permanent gully control structures. Despite the importance of erosion control measures, a holistic approach involving integrated watershed management with participation of the stakeholders is crucial for ensuring sustainable development of hilly regions.

INTRODUCTION

The predominant form of soil erosion in hill soils is water erosion. Because of the land terrain and steep slopes, hilly regions are highly prone to water erosion. Further, in many parts of the world, shifting cultivation or slash-and-burn agriculture is practiced, which aggravates the problems of soil erosion. Without the adoption of management or control practices, the erosion effects get intensified with adverse on-site and off-site impacts. Erosion management principles are based on two basic mechanisms: 1) through establishment/provision of cover on soil surface so as to protect the soil from falling raindrops; and 2) through establishment/provision of barriers so as to reduce the runoff velocity and thus decreasing the erosive power of the runoff water. A number of biological and mechanical measures are available for control and management of soil erosion. However, their use is limited by the technology cost and suitability to the particular soil, climate, and location. Important measures commonly adopted are briefly presented below.

BIOLOGICAL CONTROL MEASURES

Cropping Systems

Cropping systems with inclusion of cover crops help protect the soil surface through spread of quick canopy cover. Thus, the soil exposure to raindrops is reduced in the early crop growth stages. Canopy cover is a measure of the fraction of the soil surface covered by vegetation. Plant

canopy acts as a physical barrier and intercepts the falling raindrops and thus reduces the erosion due to splash and also the kinetic energy of the raindrops is decreased.^[1] Intercropping and strip cropping with erosion-resistant crops such as legumes (except tall and slow-growing crops like Pigeon Pea, *Cajanus cajan* L.) also help in conserving soil from erosion.

Contour Cultivation

In hilly regions, planting crops across the slope in the line of equal elevation (called contour line) is highly essential as it reduces the runoff velocity through the barrier of crop rows and the series of contour furrows that act as mini barriers. All the cultural operations are done across the slope. The effectiveness of contour cultivation depends on the soil type, slope, and crop cover, with maximum effectiveness on medium slope and deep permeable soils.^[3] The relative effectiveness decreases with increase in the degree of slope as evident from [Table 1](#).

Cover Crops

Cover crops are being promoted as an important conservation practice. Cover crops are close growing in nature with fast growth habit and quickly spread the canopy to cover the exposed soil surface. Apart from having soil conservation value, cover crops are also helpful in suppression of weeds, soil health improvement, nutrient recycling, nitrogen fixation, and increasing soil organic matter. Cover crops are mainly grown between two crop seasons. They

Table 1 Effectiveness of contour cultivation on different land slope groups.

Slope groups (% slope)	Ratio of soil loss from contour cultivation and from up and down cultivation
<1%	0.6
2–7%	0.5
7–12%	0.6
18–24%	0.9

can also be grown as rotational crops and companions to main crops. Because of the fast growth habit, they are able to capture the nutrients from the previous main crops and thus reducing nutrients from leaching losses. In addition to recovery of nutrients from previous crops, they also provide additional nutrients to the succeeding crops. For instance, legume cover crops supply 50–300 kg N ha⁻¹ to the following crops. Use of cover crops also increases biomass return to the soil and thereby increases the microbial activity and improves soil productivity.^[4]

Vegetative Filter Strips

Vegetative filter strips are an area of grass or other permanent vegetation planted between agricultural fields and streams for reducing sediment, nutrients, and other pollutants in water runoff to improve downstream water quality. These buffers are commonly used in the United States and in some parts of Europe.^[2] The filter strips are a useful conservation practice to reduce water pollution with sediment, nutrients, heavy metals, and pesticides from agricultural fields. Under sheet flow, as much as 90% of sediment is reduced by 9-m-wide filter strips. These structures are commonly followed in land slopes up to 8%.

Vegetative Grass Barriers

Vegetative grass barriers are usually two rows of grasses planted by either normal or staggered planting methods, across the slope for erosion control in arable lands. These are narrow strips of thick-stemmed, dense, and close-growing perennial grasses (Fig. 1). The grasses usually selected for the purpose are adapted to local soil type and climate. A common vegetative barrier grass species adopted across countries is the Vetiver (*Vetiver zizanioides*) grass. Normally, vegetative barriers are established at a vertical interval (VI) of 2.0 m between barriers. With vegetative barriers spaced at optimum interval, they reduce the degree of slope and gradually make the land leveled. Normally, they are effective in mild slopes with land slope of 2–6%.

Hedge Row Barriers

These biological measures are effective in arable as well as in non-arable sloping lands, with land slope up to 8%. These

Fig. 1 Vegetative barrier of grass species on arable lands.

are similar to grass barriers, but the plant species used are perennial shrubs (Fig. 2). The species should have strong rooting pattern with good canopy cover, particularly from near-ground level. Some leguminous shrub species like *Indigofera teysmannii* and *Gliricidia sepium* are very suitable for this purpose. Foliage of these species is rich in nitrogen and thus contributes to soil fertility buildup through leaf litter. To cover up the gap between two hedge plants at the ground or near-ground level, sometimes grass species are planted as grass filters, either between the two hedge plants or at staggered points in front of the hedge rows. Studies from eastern India indicate provision of grass filter strips to the hedge row barriers significantly reduces the runoff and soil loss and also contributes to additional soil moisture storage.^[5]

MECHANICAL MEASURES

Mechanical measures involve construction of mechanical barriers across the direction of flow of runoff water to retard the flow velocity. The basic principles behind planning of mechanical measures are 1) to increase the time of concentration of runoff and thus allowing more water to be

Fig. 2 Hedge row barrier of *Indigofera teysmannii* in Eastern Ghat highland zone of India.

absorbed into the soil; and 2) to break long slopes into short ones so as to maintain less than a critical velocity of the runoff water. The common mechanical measures include contour bunding, graded bunding, terracing, contour trenches, and staggered contour trenches.

Contour Bunds

Contour bunds are mechanical barriers such as earthen bunds, constructed across the slope. These are narrow-based trapezoidal embankments on contours to impound runoff water behind them so that all the impounded water is absorbed slowly into the soil profile. They are recommended for low-rainfall areas (<600 mm annual rainfall) and for permeable soils to serve as both a water and a soil conservation measure. They are effective in the 2–6% land slope range.^[4] In the events of high rainfall, they are useful by providing safe diversion of excess runoff and thus allowing deposition of suspended sediments along the bunds. Spacing between two contour bunds is fixed by the vertical interval (VI), which is directly proportional to the land slope.

Graded Bunds

Graded bunds, though similar to contour bunds, are recommended in high rainfall and poorly drained soils. In areas

with high rainfall (>600 mm annual rainfall) and in soils with poor drainage characteristics, there are chances of impoundment of runoff water and flow over the top of the bunds. Hence, a gradient is given to the accompanying channels constructed across the slope, which are thus known as graded bunds.^[4] They are recommended up to 10% land slope. The grade of the channels is decided by the soil type, and spacing between two graded bunds is determined by the VI.

Bench Terraces

Bench terracing involves converting the original ground into level step like fields constructed by half cutting and half filling and is commonly practiced in hilly regions. The factors such as soil depth, uniformity in the spread of top soil, slope of land, rainfall amount and distribution, farming practices, and the proposed crops to be grown have direct bearing on design of bench terraces. The width of the bench terraces depends upon the degree of land slope. They are of three different types: table top, outward sloping, and inward sloping (Fig. 3). In general, bench terraces are recommended for slopes up to 33%, but due to location-specific topographic features and socioeconomic compulsions, this practice is being adopted even up to 100% land slopes (Fig. 4). Although terracing makes farm operation easier, it is costly and in the initial years

Fig. 3 Schematic diagram showing types of bench terraces.

Fig. 4 Bench terracing in the northeastern hill region of India.

results in the loss of productive soil depth, leading to reduction in crop yield. Hence, in these situations, Puer-torican types of terraces are recommended in which mechanical or vegetative barriers are placed on the hill slopes so that terraces are gradually formed over a period of about 5 years. Sometimes this is also referred to as bioterracing (Fig. 5).

Adaptability of types of bench terraces

Level bench terraces (table top). These are used for paddy cultivation for providing uniform impounding and can be adopted even on mild slopes receiving medium rainfall and having highly permeable deep soils.

Inwardly sloping bench terraces. Some crops are quite susceptible to water stagnation. Hence in order to minimize losses, the terrace is provided with a water disposal channel

Fig. 5 Natural terraces formed between two rows of hedge barriers.

toward the riser of next higher terrace (in the original ground rather than on the fill portion). The inner water disposal channel has a longitudinal grade to safely dispose off excess water into the natural waterway. It is usually adopted in high-rainfall regions in deep soils with good permeability for crops that cannot withstand waterlogging such as potato and maize. These terraces help in quick and safe disposal of runoff through the drain provided on the inner side.

Outwardly sloping bench terraces. These terraces are constructed under low rainfall conditions when soil depth is a limiting factor. The farmers make the benches gradually over a long period of time with shallow permeable soils. Under this situation, water disposal channels or shoulder bunds should be constructed to allow runoff to pass safely from one terrace to another, thus preventing excess runoff from damaging the riser. Where soil depth or rainfall is not limiting, it is considered as the intermediate step for construction of either the level bench or inwardly sloping terraces. In the middle Himalayan region, 70% of the bench terraces are constructed between land slope of 50% and 70% with average outward and longitudinal slopes of 10% and 8%, respectively.

Computation of width and earthwork for terracing

Terrace spacing is usually expressed in terms of VI at which the terraces are constructed. The VI affects the depth of cutting and the height of the bund and thereby the total vertical drops. The width of the terraces should be such that it enables convenient and economic agricultural operations.

The width of terrace (W) can be computed for a given slope (s) by Eq. 1 (Fig. 6):

$$W = \frac{200d}{s} \quad (1)$$

where d is the maximum depth of productive soil range in meters, and s is the land slope in percent.

The earthwork in bench terracing can be computed as follows:

Fig. 6 Schematic diagram showing "cut and fill" in terracing.

$$E = \frac{100Ws}{8} \quad (2)$$

where E is the earthwork (m³), W is the width of terrace (m), and s is the land slope (%).

Grassed Waterways

Grassed waterways serve as safe channels for the exit of the runoff water from a watershed and are designed along the prevailing slope. The most ideal location for grassed waterways is a natural depression or drainage line. In case grassed waterways can't be located in natural courses, they are artificially constructed along the fence lines to avoid inconvenience to farm operations.

Diversion Drains

Diversion drains are provided at the top of arable area to intercept the uncontrolled flow of runoff water from the upper catchment area and to take the water safely to a watercourse. The construction of diversion drains is important since all the conservation measures in the arable area are planned with the assumption that water from the upper nonarable catchment is safely diverted. Diversion drains are provided across the slope on slight gradient, and the capacity is designed for a 10-year recurrence interval storm.

Gully Control Drainage Line Treatment Structures

Gully control structures are provided for establishment of gullies and to prevent the widening of gullies further. They help in reducing the runoff velocity and thus facilitate the establishment of vegetation so that runoff is intercepted at the vegetated locations and thus velocity is significantly lowered in the downstream flow regions. Loose boulder check dams are common type of gully control structures which are less costly and affordable by small farmers. The gully control structures are classified as temporary, semi-permanent, and permanent gully control structures.

Temporary gully control structures

These structures provide support to the vegetation during the initial period of gully establishment. The vegetation once established takes care of the gully. Temporary check dams made of locally available materials like brushwood and logwood are used in small gullies, mostly in the upper reaches where runoff is less. Brushwood check dams, loose boulder structures, gunny bag structures, and earthen gully plugs are the common temporary gully control structures.

Gunny bag structures (boribunds). These types of embankment structures are made from “gunny bags (*bori*)” using available local materials for blocking active and

Fig. 7 A view of *Boribund* structures in gullied lands.

erosion-prone first-order drains. These are made up of empty cement bags filled with sand, clay, and other locally available materials and are placed at the course of the stream to reduce the runoff velocity (Fig. 7). They are used across first- or second-order drains, particularly in places where the runoff velocity is low. The height of the boribund is usually kept at 0.9–1.5 m, and length is kept as equal to the channel width. The spacing depends upon the gradient of the channel bed.

Loose boulder/dry stone check dams

These are most widely used temporary structures in areas where stones are available in plenty (Fig. 8). As far as possible, the location of the check dam should be in the middle of a straight reach of at least 10–15 m. The check dam should be at a right angle to the straight reaches. The loose boulder check dams should have a maximum height of 1 m only. The VI between two structures should be about 1.0 m. The structures should be anchored in the sides of gully up to a length of 0.5–1 m on both

Fig. 8 Loose boulder structures.

sides depending upon site and compaction of soil of gully sides. The level of the structure should be higher at both the sides than the center portion to avoid undercutting on sides.

Semipermanent structures

These structures are placed in the middle reaches, and the life of the structures is up to 15 years. The common semipermanent structures are gabion check dams and logwood dams.

Gabion check dams. Stone wire crate or gabion check dams are commonly used for drainage line treatment in second- and third-order (main) gullies/channels.^[3] The structures are made of stones put in structures woven in galvanized iron (GI) wires (Fig. 9). They are useful for retention of debris and soil accumulation without ponding. The debris-carrying capacity in the gullies between two gabion structures reduces with time due to reduction in channel gradient. The check dam encourages good plant cover not only along the bank but also in the bed of the stream due to increased moisture regime.

Permanent gully control structures

These structures are used where vegetative or temporary structures are not adequate. The major types of permanent structures are drop spillways, drop inlet spillways, and chute spillways.^[3]

Drop spillway. It is a weir structure, and the runoff water passes through the weir opening and drops to an approximate level apron or stilling basin and then passes to the downstream channel (Fig. 10). These structures are effective to control relatively low heads and normally up to 3.0 m. They are constructed of reinforced concrete, plain concrete, rock masonry, and concrete blocks with or without reinforcement or gabions.

Fig. 9 Gabion structures as low cost gully control measures.

Fig. 10 Drop spillway as a drainage line treatment.

Drop inlet spillways. A drop inlet spillway is a closed conduit that carries water under pressure from above an embankment to a lower elevation. The usual function of a drop inlet spillway is to convey a portion of the runoff through or under an embankment without erosion. It is a very efficient structure for controlling relatively high gully heads usually above 3.0 m.

Chute spillways. A chute spillway is an open channel with a steep slope, in which flow is carried at a supercritical velocity. It consists of an inlet, vertical curve section, steep-sloped channel, and an outlet (Fig. 11). Reinforced concrete is widely used to construct chute spillways.

RAINFALL ANALYSIS: RETURN PERIOD/RECURRENCE INTERVAL

For design of soil conservation structures, the important rainfall parameters are amount, duration, intensity, and frequency (recurrence interval). The first three parameters do not need much elaboration; however, it is important to

Fig. 11 A chute structure in place across the drainage line.

Table 2 Recommended maximum design frequencies for various types of structures.

S. No.	Type of structure	Frequency (years)
1	Storage and diversion dams having permanent spillways	50–100
2	Earth fill dams storages having natural spillways	25–50
3	Stock water dams	25
4	Small permanent masonry gully control structures	10–15
5	Terrace outlets and vegetated waterways	10
6	Field diversions	15

understand the concept of return period/recurrence interval of rainfall storms or events.

The design of soil conservation structures requires information about the return period/recurrence interval of rainfall events. Return period/recurrence interval refers to the period in years during which a storm of given duration and intensity is likely to equal or exceed a given amount of rainfall intensity. It does not mean that a given rainfall/storm intensity will repeat exactly after the return period. For example, if the rainfall of 10 cm day⁻¹ at a particular place has a recurrence interval of 5 years, it means that the chances of rainfall are such that once in 5 years, rain is likely to equal or exceed 10 cm. This does not mean that a rain equal to 10 cm or more will occur after every 5 years. It may occur twice in one set of 5 years and may not occur for consecutive 8 years or so.

Recurrence interval plays a crucial role in the economic and safe design of soil conservation structures. It is essentially a compromise between the cost and risk associated with the structure. Depending upon the nature and importance of the structure and risk involved in case of its failure, a life period is assigned, and the structure is designed for the largest rainfall event that is expected to occur during that period. For example, an earthen bund may be designed with a return period of 10 years as its failure does not involve high risk. A water harvesting dam with permanent spillway, on the other hand, needs to be designed for a higher design frequency (50–100 years) storm. In cases where human life is likely to be endangered, the structure is designed for highest ever storm which might have occurred in the available record of rainfall data lasting not less than 50 years. The recommended maximum design frequencies for various types of structures are given in Table 2.

WATERSHED APPROACH

Hydrologically, watershed is a land unit from which the runoff flows to a single outlet. It can be as big as a river catchment and may be small in the size of a microwatershed

covering one or two villages. However, watershed is not only a hydrological unit but also a sociopolitical and ecological entity.

Watershed management refers to implementing land and water management methods to protect soil, water, and other natural resources within a watershed area as well as additional benefits to the downstream areas. Mere construction of soil conservation structures has failed to address the issue of integrated natural resource management in the erosion-prone hilly and rainfed regions. Thus, the conservation of natural resources is being attempted through integrated and participatory watershed approach.^[6] The soil and water conservation measures are only one component of the watershed management program. The other components include entry point activities, capacity-building program of the stakeholders, income-generating activities for landless and marginal farmers, and land-based interventions for crop and livestock development. Major objectives of the watershed programs are as follows:^[7]

- Development and efficient use of land as per the land capability;
- Efficient use of natural resources for livelihood improvement;
- Soil and water conservation and their optimum utilization;
- *In situ* conservation of rain water and water harvesting;
- Flood control and protecting water storage structures and reservoirs from siltation; and
- Maintaining ecological balance.

Abstract

Soil loss tolerance (T) values have proven tremendously beneficial in developing and evaluating conservation systems that maintain or improve the soil resource. Without them, soil conservationists, farmers, and ranchers would have little basis for evaluating the adequacy of a particular conservation system. With the additional scientific knowledge existing, we have the basis to refine T values to make them more responsive to site-specific conditions.

INTRODUCTION

Scientists first defined the *Soil Loss Tolerance* (T) value in the 1940s as “the amount of soil that could be lost without a decline in fertility, thereby maintaining crop productivity indefinitely.”^[1–3] The Natural Resources Conservation Service [formerly Soil Conservation Service (SCS)] has used T values in conservation planning since the mid-1960s. T value is most commonly defined as “the maximum rate of annual soil erosion that may occur and still permit a high level of crop productivity to be obtained economically and indefinitely.”^[4]

Although not a component of erosion prediction technologies, the T value is used as a basis for comparing estimated soil losses by prediction models to determine whether or not a particular cropping and management system is sustainable and therefore acceptable; e.g., if a particular soil under a specific cropping and management system is estimated to be eroding at 22.4 tonnes/ha/yr, and the T value for that particular soil is 9.0 tonnes/ha/yr, soil erosion would be considered excessive, and additional conservation treatment would be recommended.

Because tremendous technological advances have occurred in the area of soil fertility and amendments, on which the original definition was based, the T value concept may now be outdated. In other words, if any loss in soil fertility because of soil erosion can be replenished with commercial fertilizer, is there cause for concern about soil erosion? The answer to this question is obviously yes, especially if maintenance of our soil resource, as well as other resource concerns, is considered.

BASIS FOR T VALUES

A primary reason for setting T values was to maintain soil fertility and productivity levels. Organic matter was used to indicate the level of soil fertility present. Other soil characteristics considered included soil loss limits to prevent the formation of gullies, variation in soil type, and whether soils contained restrictive layers (e.g., claypan or heavy infertile subsoil).^[5] Early work^[3] assigned a T value of 6.7 tonnes/ha/yr for Putnam soil, and 9.0 tonnes/ha/yr for Marshall and Shelby soils, taking into account that if soil loss exceeded these rates, soil fertility levels would decline. Using available research on a limited set of soils, T values were then assigned to other soils based on interpolation.

The rate of soil formation for each soil type must also be considered in establishing a soil erosion limit. There are even less scientific data available to address this area. Estimates suggest that under natural conditions soil forms at a rate of about 2.5 cm in 300–1000 years.^[6] Under cultivation, however, soil may form at a rate of about 2.5 cm in 100 years. A research suggests that the formation of the A horizon may occur at a rate of 2.5 cm in 30 years for medium to moderately coarse-textured soils but would be slower in finer-textured soils.^[7] However, increasing the depth of a favorable rooting zone through weathering takes much longer than the development of the A horizon. One estimate indicates that we might expect to develop 1.1 tonnes/ha/yr of soil for unconsolidated parent material and much longer for consolidated parent material.^[8]

Assuming a soil density of 1320 kg/m, if the A horizon renews itself at the rate of 2.5 cm every 30 years, an

average erosion rate of 11.2 tonnes/ha/yr would maintain the A horizon. However, assuming that rooting depth is renewed at the rate of 1.1 tonnes/ha/yr from unconsolidated parent material, total rooting depth will continue to decrease even with soil erosion occurring at 11.2 tonnes/ha/yr.^[5] Therefore, if soils erode for several centuries at T levels, considerable loss in soil productivity may result.^[9] However, reducing the allowable soil loss to 1.1 tonnes/ha/yr (the level estimated to be the rate of rooting depth development for unconsolidated parent material) would likely cause significant production constraints. Hugh Hammond Bennett, the first Chief of the Soil Erosion Service, stated in 1939, “As nearly as can be ascertained, it takes nature, under most favorable conditions, including a good cover of trees, grass, or other protective vegetation anywhere from 300 to 1000 years or more to build a single inch of topsoil. When seven inches of topsoil is allowed to wash away, therefore at least 2000–7000 years of nature's work goes to waste.”^[10]

A 1956 joint conference involving the U.S. Department of Agriculture, Agricultural Research Service, and the SCS addressed the issues surrounding the establishment of T values.^[11] As a result of this conference, a committee established the following specific factors as being important in establishing T values:

- 1. Maintenance of adequate soil depth
- 2. Value of nutrients lost
- 3. Maintenance of water control structures and control of floodplain sedimentation
- 4. Prevention of gullies

- 5. Yield reduction per inch of topsoil lost
- 6. Water losses
- 7. Seeding losses

This committee also set the caveat that T values should not exceed 11.2 tonnes/ha/yr. The SCS held six regional workshops in 1961 and 1962 that resulted in T values from 2.2 tonnes/ha/yr to 11.2 tonnes/ha/yr being established in each region.^[8] Table 1 shows the percent distribution of T values in 12 soil orders occurring in the United States. Although some adjustments have been made to the criteria for establishing T values, the basic structure is in use.

EXISTING CONCERNS

Since the late 1950s and early 1960s, soil erosion prediction technology has significantly improved. The Universal Soil Loss Equation was replaced by the Revised Universal Soil Loss Equation in 1995. In addition, considerable work has been completed on process-based models for both wind and water erosion. As erosion prediction models become more sophisticated and better represent site-specific conditions, questions arise as to whether traditionally defined T values are outdated.

Because T values were developed primarily for use on cropland soils, there is a concern that they may not be applicable to permanent pasture or rangeland. For the very fragile landscapes on which rangeland often occurs, tolerable soil losses might need to be

Table 1 T values expressed in percent of soils mapped for each soil order in the United States.

Soil order	Order code	T Value (t/ha)					Total area (ha) ^a

Source: Data from Soil Survey Staff.^[12]

significantly lower than those established for similar, more fertile soils that are cropped. For example, where a maximum of 11.2 tonnes/ha/yr is recommended for soils that are cropped, a limit of 5–7 tonnes/ha/yr might be more appropriate for rangeland. In addition, sheet and rill erosion occurs less often and concentrated flow erosion is often of greater concern on rangeland than on cropland. T values, which address only sheet and rill erosion, are not applicable to concentrated flow or gully erosion. Therefore, consideration should be given to establishing T values based on the specific use of the land. For example, it is not appropriate to use a T value of 11.2 tonnes/ha/yr for a range site that would likely be devastated if more than 5 tonnes/ha of soil erosion occurred on an annual basis. Productivity of the site, potential loss of desired vegetation, and soil rooting depth must therefore be taken into consideration.

In contrast to on-site effects caused by sheet and rill erosion, off-site impacts of soil erosion—such as sediment damage, water and air quality degradation, and emission of greenhouse gases—are of greater concern. Society's increasing urban nature and environmental consciousness have made off-site concerns more important than they were at the time that soil tolerance values were established. Formally incorporating the societal costs of off-site damages into the concept of soil loss tolerance is a major challenge for the future. Some of those costs are direct and relatively easy to quantify, such as the cost of dredging navigable waterways, ditches, and reservoirs. Other costs, such as those associated with the degradation of water quality in lakes and streams, impact their use by humans, fish, and wildlife and are therefore less easily quantified.

The sediment discharge and the amount of deposition in sensitive areas resulting from the eroding fields depend greatly on the distance and the transport conditions between both areas. For example, excessive erosion on a field of several kilometers from a sensitive area is less of a potential concern than erosion on a field adjacent to that same sensitive area. Therefore, proximity to sensitive areas, as well as transport conditions, may need to be considered when establishing or revising T values. In addition, fish and other wildlife vary in their ability to tolerate sediment and associated pollutants. Some species are very sensitive, while others are not, indicating that a single tolerance value is inadequate when a broader set of concerns is evaluated.

If site-specific T values become an option, they must consider these concerns in order to be effective in protecting and enhancing all of our natural resources. In addition, a more modern approach to traditional productivity losses from erosion is needed. The short- and long-term cost and benefit trade-offs of soil conservation

can and should be addressed using state-of-the-art methods of establishing T values.

CONCLUSION

T values have proven tremendously beneficial in developing and evaluating conservation systems that maintain or improve the soil resource. Without them, soil conservationists, farmers, and ranchers would have little basis for evaluating the adequacy of a particular conservation system. Several national programs, including Conservation Compliance, Conservation Reserve Program, and the Environmental Quality Incentives program, have been implemented based, in part, on the T value concept.

Because of its widespread use in program activities, it is time to reevaluate the T value concept. Perhaps, a T value assigned to an individual soil should be viewed as a generic T value or basic starting point. Tables, equations, or process-based models could be developed to adjust the generic T value based on various conditions, such as land use, proximity to sensitive areas, susceptibility of wildlife species to sediment and associated contaminants, and other off-site concerns. For example, an assigned T value for a cropped soil may need to be reduced to maintain the ecological integrity of a rangeland site. This same T value may need to be reduced further, depending on off-site considerations, or a T value for a cropped site may need to be adjusted downward if excessive sedimentation would be detrimental to the proper functioning of an adjacent wetland.

With the additional scientific knowledge existing, we have the basis to refine T values to make them more responsive to site-specific conditions.

Erosion: Aggregate Breakdown Mechanisms

Yves Le Bissonnais

Orleans Research Center, Science of the Sun Unit, National Institute of Agronomic Research (INRA), Orleans, France

Abstract

Crusting and interrill erosion on cultivated soils result mainly from aggregate breakdown and detachment of fragments by raindrops. The measurement of fragment size distribution following breakdown and the analysis of aggregate breakdown mechanism allow the assessment of the soil's susceptibility to crusting and erosion. It will help to replace the actual empirical erodibility parameters in erosion models by physically based soil-specific characteristics. The knowledge of the different aggregate breakdown mechanisms will also allow to establish the relationship between soil properties and erosion processes.

INTRODUCTION

Aggregate breakdown influences several aspects of soil's physical behavior, such as infiltration, crusting, and erosion.^[1,2] Soil susceptibility to breakdown into finer, more transportable, particles and microaggregates is of major importance in erosion processes. Aggregate breakdown measurement is often considered as a good mean for soil erodibility assessment.^[3,4]

Various processes are responsible for aggregate breakdown. The type of breakdown process affects the intensity of aggregate breakdown and the size distribution of soil fragments available for detachment and transport. Soil particles detachability and importance of runoff volume during interrill erosion are governed by the formation of soil crust. Hydrodynamic properties and formation characteristics of soil crust are related to size distribution of breakdown products.^[5–7]

Soil loss can be described as a net balance between the detachment of *in situ* soil fragments by splash and overland flow, transport of the previously detached sediment, and deposition. In the case of interrill erosion, the detachment of soil fragments is due to the impact of raindrops (splash), and transport is principally performed by overland flow.^[8,9] These erosion subprocesses depend on the size distribution of available soil fragments provided by previous soil breakdown.

THE MECHANISMS OF AGGREGATE BREAKDOWN

Aggregate breakdown by water may result from a variety of physico-chemical and physical mechanisms and may involve different scales of soil structure from clay particle interactions to the macroscopic behavior of aggregates.^[4,10–12] Four main mechanisms can be identified from

the various reviews already available: 1) physico-chemical dispersion due to osmotic stress; 2) slaking, i.e., breakdown caused by the compression of entrapped air during wetting; 3) breakdown by raindrop impact; and 4) breakdown by differential swelling.

These mechanisms differ in many ways: in the nature of interparticle bonds and the energy involved in their disruption, in the physical and chemical conditions required for disaggregation, in the kinetics of the breakdown process, in the type of soil properties influencing the mechanism, and in the nature and size distribution of the breakdown products.

Physico-Chemical Dispersion

Physico-chemical dispersion results from the reduction of the attractive forces between colloidal particles while wetting. Stability or dispersion depends on cation size and valence. Polyvalent cations cause flocculation, whereas the monovalent cations cause dispersion. Dispersion is affected by the electrolyte concentration (EC) of the soil solution, the EC of applied water, and by the mechanical disturbance from raindrop impact or shaking.

Dispersion depends mainly on the exchangeable sodium percentage (ESP) of the soil. The defining characteristic of dispersion is the production of elementary particles rather than microaggregates. Therefore dispersion is the most effective process of aggregate breakdown, and it greatly increases the effect of the others. Dispersion generally induces very fast crusting, slow infiltrability, and great mobility of particles in water.

Breakdown by Compression of Trapped Air: Slaking

Slaking is caused by the compression of air entrapped inside aggregates during wetting. It occurs when dry

Fig. 1 Aggregate stability (percentage of fragments $>200\ \mu\text{m}$ after immersion of 3–5 mm aggregates in water) as a function of initial water content and clay percentage, for various cultivated soils from northern France.

Source: From Le Bissonnais.^[4]

aggregates are immersed in water or rapidly wetted. The effect of trapped air depends on the volume of air inside the aggregates, on the rate of wetting, and on the shear strength of wet aggregates. Slaking occurs even without any shaking of soil in water, although shaking increases the effect of slaking because of additional mechanical breakdown or dispersion. Le Bissonnais^[4] found that slaking decreases as the initial moisture content increases until saturation is reached (Fig. 1). This is due to the reduction of the volume of air that is entrapped during wetting and also to the reduction of gradients of matric potential. Fig. 1 also shows that, in the range of 100 to 300 g kg^{-1} of clay content, breakdown decreases when clay content increases.

The fragments resulting from slaking are mainly microaggregates, and they increase in size with increasing clay content. This can be explained according to the model of textural porosity.^[13] The clay volume and the resistance of clay bonds between skeleton grains increase with clay content, so the elementary assemblages of primary particles are bigger.

Mechanical Breakdown by Raindrop Impact

Mechanical breakdown of aggregates by raindrop impact usually occurs in combination with the other mechanisms if the kinetic energy of raindrops is great enough. The importance of this effect is clearly demonstrated by the role of vegetation cover or mulch, which protects the soil surface against such impact. Mechanical breakdown by raindrop impact plays a dominant role in wet soils because the aggregates are weaker when the soil is wetter. Also, under “undrained” conditions, the compressive stress of the raindrop impact is transformed into lateral shear stress that causes the fragments to detach and project. Therefore raindrop impact not only detaches but also displaces previously detached fragments.^[2,5] This mechanism is called the splash effect. Because very stable macroaggregates can be moved by splash, a discrepancy between aggregate

stability and splash measurement under rainfall may be expected. The fragments resulting from raindrop detachment are generally small, being either elementary particles or small microaggregates ($<100\ \mu\text{m}$).

Breakdown by Differential Swelling

Differential swelling and shrinkage during wetting and drying of clay soil result in a microcracking of aggregates. It depends on the same properties as slaking, including the rate of wetting. It produces microaggregates that are about the same size and type as microaggregates resulting from slaking of initially wet soils. However, we make the distinction between the two mechanisms because physical processes are different, although some authors use the word “slaking” for both mechanisms. Breakdown by slaking decreases as clay content increases, whereas breakdown by differential swelling increases with increasing clay content. The consequences of breakdown by differential swelling (microcracking) on infiltration are less severe than those of slaking or dispersion because of the larger size of the resulting fragments. However, microcracking may accelerate the formation of structural crusts by reducing the mean aggregate size.

Soil Properties Influencing Aggregate Breakdown

The main soil properties influencing aggregate breakdown and erosion are soil texture, clay mineralogy, organic matter content, type and concentration of cations, sesquioxide content, and calcium carbonate content, with multiple interactions between these properties that can modify their individual influence.^[10,11] ESP affects particle dispersion, iron and aluminum oxides, and oxyhydroxide cement aggregates, particularly for tropical and lateritic soils. Organic matter protects the surface against raindrop impact; it is a bonding agent between mineral soil particles and it may impart hydrophobic characteristics that reduce slaking.

THE RELATIONS BETWEEN AGGREGATE BREAKDOWN AND ERODIBILITY

Soil erodibility may be defined as the inherent susceptibility of soil to detachment and transport by rain and runoff. Relations exist between aggregate breakdown, crusting, and erosion.^[5,6]

Crust Formation

For most cultivated lands, erosion results from runoff caused by the decrease of infiltration rate due to surface sealing and crusting by rain. The infiltration rate may decrease to as little as 1 mm hr⁻¹. Another effect of sealing is the reduction of surface roughness that results in smaller depressional storage and in more uniform flow over the surface.

Two main morphological types of crust can be distinguished. Structural crusts are formed by a reorganization with little displacement of fragments and without sorting and sedimentation. They result from the gradual packing and coalescing of particles and small aggregates, which are mainly produced by slaking and microcracking. Depositional or sedimentary crusts result from fragment and particle displacement and sorting under ponding conditions. The mechanisms are mainly dispersion and mechanical breakdown by raindrop impact. These two crust morphologies correspond to two successive stages in a general pattern of seal and crust development.^[14] Structural crusts are generally formed during the preponding phase, whereas depositional crusts and erosion are co-incident. A distinction between the various mechanisms of breakdown may help to explain the dynamics of surface crusting and erosion.

Whether they are primary particles or microaggregates, fragments <100 µm in size packed together result in pores smaller than 15 µm. It can be shown from Poiseuille's law, which describes flow discharge in a

cylinder and the measurements of raindrop pressure, that for pores <15 µm in size, frictional effects reduce water penetration:

$$\text{Poiseuille's law: } Q = \pi R^4 P / 8 \eta L$$

With Q = flow discharge (m³ sec⁻¹), R = radius, P = pressure, η = viscosity, and L = length.

Image analysis and mercury porosimetry support this theoretical approach and show that if all the pores are <15 µm in size then infiltration almost ceases.

Soil Fragments Release

In addition to being the primary cause of crusting, aggregate breakdown is responsible for the production of microaggregates and particles, which are easily transported by splash and runoff. This effect of breakdown is particularly important in interrill erosion, where the flow detachment capacity is limited (Fig. 2). The conceptual models for soil erosion in interrill areas divide soil erosion into subprocesses: detachment, transport, and sedimentation. In the process-based model developed by Hairsine and Rose,^[9] it has been supposed that soil detachment is due to raindrop impacts and that the only role of overland flow is to transport downslope the detached aggregates. This model calculates the fragment size distribution leaving a uniform area through the concept of settling velocity classes. It describes the rate of rainfall detachment and uses an empirical detachability parameter. We hypothesize that aggregate breakdown measurement can be used to model the size distribution of fragments resulting from raindrop effect.

Moreover, the fragment size distributions of splash and overland flow sediment have been observed to be finer than the original soil, as a result of selective removal of silt and clay-sized particles or preferential deposition of coarse fragments. However, the size selectivity of wash and splash subprocesses has generally been studied in comparison

Fig. 2 Conceptual modeling of interrill erosion in subprocesses: breakdown, mobilization, and transport/sedimentation. (A) Initial aggregates; (B) breakdown into fragments; (C) raindrops mobilize fine fragments; (D) available for transport by overland flow for the finest; (E) or to sediment for the coarsest.

Fig. 3 Fragment size distribution resulting from breakdown of 3–5 mm aggregates for a silt loam. (A) Comparison between size distribution corresponding to different heights of cumulative rainfall and (B) the three aggregate stability treatments. Three granulometric size ranges with specific dynamics can be distinguished in (A). Standard errors are represented for each aggregate stability treatment in (B).

with the soil matrix without considering the aggregate breakdown. Knowing the dynamic of size distribution of breakdown products helps understand both the sealing processes and the selectivity of splash and overland flow

(Fig. 3). Table 1 gives the various classes of values for aggregate stability expressed as mean weight diameter (MWD)^[4] and the relationship with crusting and interrill erodibility.

Table 1 Classes of aggregate stability, crustability, and interrill erodibility according to MWD values measured with the three treatments offered.

Class	Examples of soil	MWD value (mm)	Aggregate stability	Crustability and interrill erodibility
1	Sodic soil, silty soil...	<0.4	Very unstable	Systematic crust formation very high erodibility
2	Silty clay loam with low organic matter content...	0.4–0.8	Unstable	Crusting frequent high erodibility
3	Silty clay loam with high organic matter content...	0.8–1.3	Medium	Moderate crusting moderate erodibility
4	Clay loam...	1.3–2.0	Stable	Crusting rare low erodibility
5	Heavy clay or organic soil...	>2.0	Very stable	No crusting very low erodibility

Note: The differences in MWD values for the three treatments for a given soil correspond to the differences in soil behavior, which varies with initial water content and rainfall characteristics.

CONCLUSION

Crusting and interrill erosion on cultivated soils result mainly from aggregate breakdown and detachment of fragments by raindrops. The measurement of fragment size distribution following breakdown and the analysis of aggregate breakdown mechanism allow the assessment of the soil's susceptibility to crusting and erosion. It will help to replace the actual empirical erodibility parameters in erosion models by physically based soil-specific characteristics. The knowledge of the different aggregate breakdown mechanisms will also allow to establish the relationship between soil properties and erosion processes.

Abstract

Soil erosion by wind and water degrades our soils by removing material from the fertile topsoil. Windstorms and rainstorms detach and transport soil particles high in nutrients and organic matter. The result is a soil surface with reduced plant-available nutrients, high in bulk density, and low in porosity and capacity for water intake.

SOIL EROSION AND ITS CONTROL

In regions with adequate rainfall, nature's way of protecting the soil is for vegetation to grow during periods of adequate rainfall and temperature, die during periods of low rainfall or temperature, and emerge again to start the next cycle. Either growing plants or plant residue would cover the soil to protect it from erosion. During the process of soil formation, the cycle of growing plants and decaying residue would provide protection for the soil while new soil developed.^[1]

Mechanization has, over the 20th century, allowed farmers to till the soil and plant row crops continuously under intensive cultivation. This has seriously altered nature's system of producing topsoil and protecting the soil from erosion. Under intensive, conventional tillage, soils are left unprotected and exposed to wind, rainfall, and runoff. Erosion has reduced the depth of topsoil, altered its natural tilth and structure, and reduced its productivity. Further advances in technology have made it possible to employ techniques similar to nature's methods of protecting the soil during crop production by leaving the previous crop's residue on the soil surface, adding nutrients to the soil, and maintaining its tilth and structure.^[1] Of all the tools that technology has made available to farmers to control erosion, the most efficient and economical are agronomic practices—those that involve management practices that protect the soil during production of crops.

AGRONOMIC PRACTICES THAT CONTROL EROSION

Types of Agronomic Practices

The more common agronomic practices used to control erosion on cropland are described as follows:

Residue management

Residue management is managing the amount, orientation, and distribution of crop and other plant residue on the soil surface year-round while growing crops.^[2] Crops are grown in narrow slots, in residue-free strips in previously untilled fields, or in fields where the entire surface is tilled prior to planting. It includes limiting or reducing tillage to leave more residues on the surface. An increase in ground cover of just 10% can reduce soil loss by as much as 20%.

Conservation tillage

Conservation tillage is any tillage and planting system that covers 30% or more of the soil surface with crop residue, after planting, to reduce soil erosion by water. Where soil erosion by wind is the primary concern, any system that maintains the equivalent of at least 1120 kg/ha (1000 lb/acre) of flat, small grain residue on the soil surface throughout the critical wind erosion period qualifies as conservation tillage.^[3] Types of conservation tillage

include no-till, strip-till, ridge-till, and mulch-till. With this agronomic practice, tillage tools are selected and operated to maximize the amount of residues left on the surface. Weed control is accomplished with a combination of herbicides and cultivation.

Contour farming

Contour farming is tillage, planting, and other farming operations performed on or near the contour of the field slope.^[2] Crops are planted around the hill nearly on the level rather than up and down the hill. This makes many short slopes out of one long slope. Contouring can reduce erosion by 50% in many instances.

Contour strip cropping

This is growing row crops, forages, small grains, or fallow in a systematic arrangement of equal width strips on or near the contour of the field slope.^[2] This practice involves a combination of crop rotation and contouring. Contour strip cropping can reduce soil loss by 75% in many instances (Fig. 1).

Contour buffer strips

These are narrow strips of permanent, herbaceous vegetative cover established across the slope. These strips are alternated down the slope with parallel, wider cropped strips.^[2] The permanent vegetation in the buffers is typically grass, legumes, or a grass-legume mix. Contour buffer strips can reduce erosion by 60% in many instances.

Fig. 1 A field with a contour strip cropping system. Strips of corn are alternated with strips of a hay crop. Planting is on the contour.

Source: Photo courtesy of USDA, Natural Resources Conservation Service.

Filter strips

A strip or area of herbaceous vegetation situated between cropland, grazing land, or disturbed land (including forest land) and environmentally sensitive areas.^[2] Typically, a filter strip is placed at the base of a slope to filter sediment and other contaminants from runoff water before they reach offsite areas or bodies of water.

Crop rotation

This involves growing crops in a recurring sequence on the same field. Erosion control is achieved by changing the crops year by year to alternate high residue-producing crops with lower residue producers, close-growing crops with row crops or perennial crops with annual crops. Some rotations can reduce erosion by 60%.

Cover crops

Grasses, legumes, forbs, or other herbaceous plants established for seasonal cover and conservation purposes are known as cover crops.^[2] Cover crops temporarily protect the soil during seasons when major crops are not growing (Fig. 2).

Grassed waterways

These are natural or constructed channels that are shaped or graded to required dimensions and established with suitable vegetation.^[2] This practice is used where water usually concentrates from terraces, diversions, concentrated flow channels, or natural waterways as it runs off a field. Grassed waterways will slowdown water and

guide it off the field, significantly reducing gully erosion.

Erosion Control with Surface Cover

Each of the agronomic practices listed previously utilizes surface cover to control erosion. Surface cover is the single most important agronomic factor in determining soil loss. Surface cover affects erosion by water by reducing the transport capacity of runoff water, by causing deposition in ponded areas, and by decreasing the surface area susceptible to raindrop impact. It also protects the soil surface from erosive winds. Surface cover includes the live plant canopy as well as plant residue.

CROP RESIDUE MANAGEMENT WITH CONSERVATION TILLAGE

The remaining section discusses in greater detail the two most important agronomic practices for controlling erosion—crop residue management and conservation tillage. Crop residue management is an “umbrella” term encompassing several conservation tillage systems. In the 1960s, the terms *minimum tillage* and *reduced tillage* were used to refer to less extensive tillage operations during the production of agronomic crops. In the 1980s, the term *conservation tillage* was used to refer to any tillage and planting system that left at least 30% of the soil surface covered by plant residue. The term *crop residue management* has evolved to address the various methods and benefits of surface residue in reducing erosion.

Crop residue management is any tillage and planting system that uses conservation tillage (preferably no-till) or another system designed to retain all or a portion of the previous crop's residue on the soil surface.

Conservation tillage, defined earlier, is any tillage and planting system that leaves more crop residue on the soil surface after planting to reduce soil erosion. Types of conservation tillage include:

- No-till/strip-till—the soil is left undisturbed from harvest to planting except for strips up to one-third of the row width (strips may involve only residue disturbance or may include soil disturbance). Planting or drilling is accomplished using disc openers, coulters (s), row cleaners, in-row chisels, or rotary tillers. Weed control is accomplished primarily with herbicides. Cultivation may be used for emergency weed control.^[4] Other common terms used to describe no-till include direct seeding, slot planting, zero-till, row-till, and slot-till.
- Ridge-till—the soil is left undisturbed from harvest to planting except for strips up to one-third of the row width. Planting is completed on the ridge and usually involves the removal of the top of the ridge. Planting is

completed with sweeps, disk openers, coulters, or row cleaners. Residue is left on the surface between ridges. Weed control is accomplished with herbicides (frequently banded) and/or cultivation.^[4] Ridges are rebuilt during row cultivation (Fig. 3).

- Mulch-till—full-width tillage involving one or more tillage trips which disturbs all of the soil surface and is done prior to and/or during planting. Tillage tools such as chisels, field cultivators, disks, sweeps, or blades are used. Weed control is accomplished with herbicides and/or cultivation.^[4]

Table 1 shows average amounts of residue cover left after various tillage operations in corn and soybeans.^[5] The residue left after harvesting soybeans was 83%, and that left after corn was 93%. Both levels gave very good erosion control compared with bare soil. The loss of erosion control because of the reduction in residue cover is evident, especially for fragile residues like soybean residue.

Crop residue management utilizes agronomic practices for the entire cropping year. A crop rotation sequence is chosen to include high residue producing crops. A crop is planted that will provide residue to meet a specified goal, such as reducing erosion to a specified level. Planting in narrower rows and at higher plant populations will create more residue. Cover crops can be used when residue from the major crop is insufficient. When no-till is not utilized, tillage operations are delayed until near planting time instead of tilling soon after harvest. With mulch-till, tillage is performed at shallower depths, with fewer passes across the field. Tillage tools are used that bury less residue compared to conventional tillage. At harvest, residue is distributed

Fig. 3 Corn growing in a ridge till system. During planting, the ridgetop was cleared and the seed planted. Residue is left on the surface between ridges. The ridges will be rebuilt during cultivation as the crop grows.

uniformly over the soil surface, and baling, grazing, burning, and other operations that remove residue are eliminated.

The effectiveness of residue cover in reducing erosion varies, as shown in Fig. 4. However, as this figure illustrates, even at relatively low residue cover levels, residue cover is highly effective. In Fig. 4, residue effectiveness is expressed as a b value. Fields easily eroded by flow, such as thawing soils where rill erosion

**Fig. 4** Effect of residue cover and b values on the surface cover subfactor for smooth field surfaces in the Revised Universal Soil Loss Equation.

Source: From Renard, Foster, et al.^[6]

is the primary mechanism of soil loss, have a b value of 0.05. Fields with highly cohesive soils, such as with long-term no-till where interrill erosion is the primary mechanism of soil loss, have a b value of 0.025. Fields that are regularly tilled have an intermediate b value of 0.035.^[6]

Residues vary in their effectiveness, depending on their size and weight, as shown in Fig. 5.^[6] For a given weight, different kinds of residue provide varying amounts of surface cover. For example, 2690 kg/ha (2400 lb/acre) of cotton residue provides 45% surface cover. The same weight of corn provides 60% surface cover, and that weight of soybean residue provides nearly 85% cover.

Leaving crop residue on the soil surface has a number of advantages over tillage that leaves the soil surface nearly bare. The most significant advantage is the greatly reduced erosion. Other advantages include the potential for increased yield due to water conserved by surface residue, lower soil temperatures in warmer climates, improved soil quality over time due to increased organic matter levels, and reduced input of time, labor, and fuel.^[7]

Success of agronomic practices, such as crop residue management and conservation tillage to control erosion, has been proven by the increasing rate of acceptance and use by farm operators. Success is due in part to the improved effectiveness and reduced cost of herbicides. Success is also due to improvements in tillage tools that leave more residue on the surface and planting equipment that works well in high-residue conditions. Finally, farm operators measure success through economics. The reduction in the number of tillage operations, the size and

**Fig. 5** Relationship of residue amount to percent residue cover for various crops.

Source: From Renard, Foster, et al.^[6]

number of tractors, fuel used, and maintenance costs are important considerations in making the decision to use crop residue management practices.

Erosion: Assessment

John Boardman

Department of Geographical and Environmental Science, University of Cape Town, Cape Town, South Africa and Environmental Change Institute, University of Oxford, Oxford, U.K.

Abstract

Soil erosion is the loss of soil from the surface of the earth. It is a two-stage process with detachment of soil particles preceding transport by the agency of water or wind. It is a natural process occurring at relatively low rates but which may be accelerated by human actions. Erosion is driven by both socioeconomic (“ultimate factors”) and physical factors such as slope, soil, and rainfall (“proximal factors”). Most erosion is associated with the formation of rills and gullies. Erosion has serious impacts on the fertility of soils, on water quality, and on reservoir storage capacity. Methods of assessing erosion include experimental plots, sediment yield in rivers, field monitoring, remote sensing, Cesium-137, historical analysis, expert opinion, and modeling. Combinations of these have often been used. Assessment of actual and potential erosion is necessary so that measures can be taken to prevent the loss of soil and limit the off-site impacts of erosion. A range of conservation measures have been used with varying degrees of success.

INTRODUCTION

Soil erosion is the loss of soil from the surface of the earth (Fig. 1). It is a two-stage process with detachment of soil particles preceding transport by the agency of water or wind. It is a natural process occurring at relatively low rates, which may be accelerated by human actions. Most erosion is associated with the formation of rills and gullies. Erosion has serious impacts on the fertility of soils, on water quality, and on reservoir storage capacity. Assessment of actual and potential erosion risk is necessary so that measures can be taken to prevent the loss of soil.

Agents of erosion are wind, water, and gravity (causing mass movement). Movement of people and animals may contribute, and soils will be more susceptible if weakened by weathering (wetting and drying, frost, etc.).

Erosion is an important contributor to global soil degradation. It is also a major component of desertification. Under semiarid conditions, vegetation damage typically precedes erosion. If climate variability is a major influence, then degradation may be cyclic, interspersed with periods of improved land quality. Frequently, because of population pressure, degraded land does not recover.

The major impact of soil erosion is on agricultural land, both arable and grazing. Other areas of concern are construction sites and protected natural areas (e.g., footpath erosion in National Parks).

This entry is mainly concerned with erosion by water that globally appears to affect twice the area of wind erosion.^[1] Overgrazing as a cause of erosion is very widespread but is difficult to classify as it often leads to erosion by water and, in some areas, by wind.

The causes of erosion may be regarded as: 1) proximal and 2) ultimate. Proximal causes relate to physical factors such as rainfall, runoff, wind velocity, gradient, and soil type. Ultimate causes relate to socioeconomic conditions that influence farmer decision making and therefore land-use and farming practices. Important farmer decisions concern what crops to plant, where to plant them, and how to plant them. Such decisions are strongly influenced by farmer attitudes and traditions, community views and, especially in the developed world, by government support for agriculture. Some such support may be regarded as a “perverse subsidy” in that it leads to unwanted and unforeseen environmental impacts including erosion and pollution; examples include European Union support for almonds in Spain,^[2] land leveling in Norway,^[3] and olive oil production in Spain.^[4] A major socioeconomic impact on eastern European landscapes was the collectivization of agriculture under Communism.^[5,6]

The relationship between population growth, food production and, exploitation of the soil is suggested by Montgomery (p. 84):^[7]

A fundamental model of agricultural development in which prosperity increases the capacity of the land to support people, allowing the population to expand to use the available land. Then, having eroded soils from marginal land, the population contracts rapidly before soil rebuilds in a period of low population density.

Major texts on erosion, its causes and consequences include those by Bennett,^[8] Blaikie,^[9] Morgan,^[10] Boardman and Poesen,^[11] and Montgomery.^[7]

Fig. 1 Severely eroded winter wheat fields, South Downs, United Kingdom, October 1987.

SCALE AND EXTENT OF EROSION

Rates of erosion on grassed or wooded areas are usually below 1 t/ha/yr. Rates of soil formation are very low—similar to natural rates of erosion. The oft-quoted USDA figure is 1 inch per 500 years which is about 0.6t/ha/yr.^[7] Erosion in excess of this figure means the loss of, or decline in, a finite resource. Erosion rates on farmland in temperate areas occasionally exceed 100 t/ha/yr. On the Loess Plateau of China, 7.2 Mha was reported to have erosion rates in excess of 100 t/ha/yr.^[12]

Hotspots of global erosion are difficult to define and rank due to lack of or unreliable data. However, we may suggest the following:^[13]

1. Loess plateau, the Yangtze basin, and the southern hill country of China
2. Ethiopia
3. Swaziland and Lesotho
4. The Andes
5. South and East Asia
6. Iceland
7. Madagascar
8. The Himalayas
9. The West African Sahel
10. Caribbean and Central America

There is very limited data for some of these areas, particularly the Andes and Madagascar. If areas that have been severely affected in the past and to some extent are more vulnerable are to be included, then the list would be extended:

1. The Dust Bowl in the 1930s in the United States (parts of Colorado, Kansas, New Mexico, Texas, and Oklahoma)^[14] (Fig. 2)
2. The Virgin Lands Project of the former Soviet Union^[15]
3. The Mediterranean basin^[16]

Fig. 2 Dust storm approaching Stratford, Texas Dust Bowl surveying in Texas, April 18, 1935.

Source: Image ID: theb1365, Historic C&GS Collection, NOAA George E. Marsh Album.

IMPACT OF EROSION

The following are the impacts of erosion:

1. On-site, which includes loss of crop, seeds, and fertilizer and thinning of the soil layer thus directly affecting present and future productivity. The amount of yield reduction is disputed with work suggesting a figure of 4% per 10 cm of soil loss.^[17] In extreme cases, land may become unworkable or unprofitable because of soil loss and nutrient depletion, as in the case of badlands (Fig. 3). Montgomery discusses many cases where land is abandoned and farmers move on, e.g., 18th century tobacco growing in Virginia, Georgia, and the Carolinas or the Amazon lowlands (p. 118).^[7] This process may result in exploitation of less suitable land or land at greater risk of erosion e.g., Rome (p. 62).^[7]
2. Off-site, where people, water/air, or property not directly responsible for erosion are affected. Runoff from agricultural land generally transports sediment

Fig. 3 Badlands, northern Spain.

particles and attached phosphorous and pesticides. Impacts include dam sedimentation,^[18] pollution of water courses,^[19] and property damage by muddy floods.^[20]

Costs of erosion are underresearched. This is partly because it is difficult to put a value on soil. As soils thin crop yields decline or they are artificially enhanced by the use of fertilizers. This is a cost which less developed societies cannot afford. Serious soil depletion results in abandonment and migration (see above). Costs resulting from off-site impacts are easier to estimate; e.g., water cleaning costs in England and Wales are estimated at several hundred million pounds per year for the removal of nitrates, phosphates, and pesticides, some of which are associated with runoff and erosion events.^[21] The costs of muddy floods in central Belgium range from 16 to 172 million euros per year.^[22] Fine-particle sediments (mainly of agricultural origin) affect fish spawning in gravel-bedded rivers.^[23,24] Sedimentation of ports is recorded from the Mediterranean and from the eastern states of the United States (p. 139).^[7]

Impacts may also be seen as either immediate or long term. The former includes the formation of gullies, the burial of crops, and the flooding of houses, and the latter refers to the gradual thinning of soils or sedimentation of reservoirs. Unfortunately the long-term effects are easy to overlook. Societies in the Middle East, Rome, Greece, MesoAmerica, etc. have all been seriously affected by soil loss.^[7]

EROSION ASSESSMENT

Erosion assessment may describe the “actual” risk of erosion: the Global Assessment of Soil Degradation project (GLASOD) is an example of this type of assessment applied globally.^[1] Similarly, Canada has published maps of the risk of wind and water erosion at the provincial level.^[25] New Zealand has combined, on single maps at 1:250,000 scale, the actual and “potential” risk of erosion.^[26] Potential in this case refers to a change of land use to pastoral or arable. Maps from the CORINE project show actual and potential soil erosion in Southern Europe, and the latter is defined as the worst possible situation that might be reached.^[27]

Erosion assessment may focus on changes through time in the same area. Trimble^[28] has measured and modeled changes in erosion and deposition rates in the Coon Creek catchment in Wisconsin since the beginning of European settler farming in the 1850s. This study relates erosion to land use change, management, and conservation techniques, as well as to the capacity of rivers to transport eroded materials. It therefore links on-site and downstream effects through time and space. Erosion rates since Neolithic clearance have been modeled on the loessic soils of the South Downs, United Kingdom. This

assessment is based on changing land use, climate, soils, and farming practices (Fig. 4).^[29] Assessment of erosion and its impacts may be combined in complex scenarios of change involving population pressure, e.g., Hurni for Ethiopia.^[30]

Modeling constitutes an important approach to erosion assessment. This is for several reasons: many areas lack the data that allow direct estimates of erosion; modeling may be based on scenarios of future land use or climate and therefore estimates may be made of erosion under assumed conditions; and application of a model may be far less expensive and time consuming than field surveys.

The spatial scale of modeling may vary from a few square meter to thousands of square kilometer. The global change and terrestrial ecosystems model evaluation exercise divides models into field, catchment, and landscape, based on spatial scale.^[31] Resolution of erosion models is determined by grid size, i.e., km² grid size used in CORINE for Southern Europe and the 250-m grid used in the maps of seasonal erosion risk in France.

Assessments are frequently expressed in map form.^[32] Landscape features indicative of erosion may be mapped as a record of an actual event or series of events. In arable landscapes, features may be temporary; thus rills, ephemeral gullies, and fans are usually plowed out annually, e.g., erosional features produced as a result of a snowmelt event in May 1993 in Slovakia.^[5] In semiarid, grazed landscapes erosional features may become permanent, e.g., gullies and badlands. Assessments should distinguish features active at the present time from those that are inactive and represent erosion under former conditions.

Several methods of erosion assessment are commonly used and Table 1^[33] and will be reviewed briefly.

1. Small experimental plots in the laboratory or in the field, and these may operate with natural or simulated rainfall^[34] (Figs. 5 and 6). They are assumed to represent larger parts of the landscape. Results are frequently extrapolated to fields or catchments and are used as input to models. Extrapolation from small plots to regional, national, or continental size areas is not acceptable.^[35]
2. Sediment yield of rivers represents the net loss of soil from a catchment.^[36] Erosion rates on fields may be very different owing to storage of soils between the field and the river. Highest rates of sediment yields from a large river are from the Yellow River, China, with an average silt content of 38 kg m⁻³.^[12] Rivers of east and south Asia deliver about 67% of the sediment reaching the world's oceans, and rates are highest in this region owing to tectonic uplift and steep slopes, high rainfall, deforestation, and population pressure resulting in

Fig. 4 Simulated annual erosion rates and surface stone content for a “thin” soil profile (1.22 m depth to chalk) on the South Downs, Southern England.
Source: Adapted from Favis-Mortlock, Boardman, et al.^[29]

intensive farming activities.^[37] Alternatively, the sediment yield from river basins may be estimated by measurement of the volume of sediment trapped in a still water body such as a lake, reservoir, or pond. A date for the construction of a reservoir are often known. Sediment including bedload will be

trapped. Losses in water passing through the dam may be estimated (trap efficiency). The advantage of this method is the possibility of medium-term records of >100 years.^[38] Sediment yield to three small dams in the Karoo, South Africa, is estimated at 115, 357, and 654 t/km²/yr for a period of

Table 1 Assessment methods: their merits and limitations.

Assessment method	Merits	Limitations
Experimental plots in laboratory or field	Control over erosion factors; ease of measurement of runoff and soil	Small size; difficult to extrapolate to larger areas
Sediment yield of rivers	Ease of measurement; may cover >100 years if reservoir sediments used	Measures total soil lost from watershed, not from specific areas
Field monitoring	Records soil lost from rills and gullies; covers large areas; inexpensive	Gives very approximate amounts of soil lost
Remote sensing	Covers large areas and may cover long time-span	Limited availability for many areas; may not be suitable for small scale features
Cesium-137	Gives 55-year average	Many unknowns; unreliable without careful calibration; expensive and time-consuming
Stratigraphy and pedology	Deposited soil may contain artifacts; suitable for long time period studies	Scarcity of suitable sites; low precision of some dating methods
Expert opinion	May reveal unrecorded information	Subjectivity: difficult to compare different areas
Models	Objectivity; ease of use even by “non-experts”; numerical output	Availability of data; complexity of process descriptions; frequent lack of validation

Fig. 5 Experimental plot (flume), University of Toronto.

65 years. These rates are adjusted to take into account trap efficiency, and the contrasts are due to differences in land use within the catchments.^[39]

Similar approaches have been used in Australia^[40] and in Ethiopia.^[41]

3. Field monitoring is defined as “field-based measurement of erosional and/or depositional forms over a significant area (e.g., >10 km²) and for a period of >2 years.”^[42] Regular measurements of volumes of soil loss from rills and gullies or deposited in fans are made. Notable examples are the monitoring of 17 localities in England and Wales during 1982–1986,^[43] a 10-year program on the South Downs, England during 1982–1991,^[44] monitoring of ephemeral gullies in Belgium during 1982–1993,^[45] and a long-term monitoring scheme in the Swiss midlands.^[46,47]
4. Simple techniques of measurement and assessment of erosion suitable for Less Developed Countries include pedestal height, depth of armor layer, plant/tree root and fence post exposure, tree mounds, and build up of sediment behind barriers and in drains.^[48] Many

Fig. 6 Experimental plots, South-Limbourg, the Netherlands.

Fig. 7 Erosion pin site in the Karoo, South Africa.

studies have used erosion pins to assess rates of erosion over time (Fig. 7). These are particularly suited to bare degraded land such as badlands. Rates may be related to topographic position, presence of vegetation, weathering, and rainfall/wind factors^[49] (Fig. 8).

5. Remote sensing is used increasingly in erosion assessment. For rill and gully erosion, it may be used as a locational technique to allow detailed field measurements to be made at selected sites. Gullies and badlands may be identified on black and white air photographs of 1:20,000 scale, and in the Karoo of South Africa, comparisons have been made between the extent of gullying in 1945 and 1980.^[50] Also in South Africa, in a pioneering study, Talbot mapped gullying in the Swartberg resulting from land conversion to wheat farming^[51] (Fig. 9). The extent of Icelandic land degradation has been assessed using Landsat imagery.^[52]
6. Cesium-137, derived from weapons testing since 1954, is used as a tracer to assess amounts of erosion and deposition. Annual average rates for the last ca. 55 years are estimated by measurement of the amount and distribution of cesium in comparison with an uneroded reference site.^[53] Studies have been carried out in Australia, Canada, China, the Netherlands, Poland, Thailand, United Kingdom, and United States. However, results are controversial with particular issues regarding the original assumed regular distribution of cesium across the landscape via the assumed homogenous spatial distribution of rainfall, and the assumption that cesium “sticks” to fine soil particles in a predictable way. These assumptions have been strongly challenged, and erosion rates obtained using this technique appear unreliable.^[54]
7. Total amounts of soil loss since a historical baseline such as woodland clearance or the beginning of European settlement have been assessed by comparison of existing soil profiles with uneroded ones. Evans estimates historical losses of topsoil of 150–250 mm in

Fig. 8 Average rates of erosion for eroding pins at two sites in the Karoo, South Africa, plotted against rainfall amount for each measurement period.

lowland England and Wales, much of which is stored as alluvium and colluvium.^[55] Sedimentation above marker horizons in reservoirs may be used to compute sediment yield for periods of time.^[39] Pedological and stratigraphic approaches have also been used to

Fig. 9 Severely gullied hill country ca. 8 km northwest of Durbanville, South Africa. Gullies are on ploughed land. Photography March 1938; the land had been abandoned by 1944.

Source: Adapted from Talbot.^[51]

assess the effect of past extreme events, e.g., the major storms and floods in Germany in the early 14th century.^[56]

8. Expert opinion has been used to assess erosion on a regional or global scale. GLASOD assesses erosion at a global scale (10 M).^[1] A total of 12 degradation types are recognized under the broad headings of water erosion, wind erosion, chemical deterioration, and physical deterioration. The “degree” of degradation is assessed for each mapping unit, as is its “relative extent.” A combination of degree and relative extent gives an assessment of “severity” which is expressed in “severity classes” and mapped in four colors. However, there is evidence that GLASOD is a very imperfect predictive tool. Van-Camp et al.^[57] are particularly critical and suggest that the GLASOD approach should be abandoned: comparison with maps and data for Spain show that assessment of water erosion was poor.^[58] GLASOD has also been assessed by other authors.^[59] At a more local and detailed level, expert opinion appears more reliable, e.g., a South African assessment.^[60]
9. Assessment of erosion has frequently been based on the application of models. The Universal Soil Loss Equation (USLE) is most widely used because of its simplicity and low-level data requirements.^[61] Further developments in modeling have concentrated on simulation of erosional processes and computerization. Models may be used to estimate average, long-term erosion rates under specified conditions (USLE), or to assess the effect of a particular rainfall/runoff event,

e.g., EUROSEM.^[62] Erosion models have also been used to predict wind erosion, and to assess chemical losses in solution, or attached to soil particles (for reviews, see Morgan).^[63]

CONTROLLING SOIL EROSION AND OFF-SITE IMPACTS

Controlling soil erosion is based on two principles, protecting the soil from runoff or wind by providing vegetative protection, or reducing the slope and thereby decreasing water velocity. Erosion generally takes place on bare soil (Fig. 1), and therefore the protection of a crop or crop debris at vulnerable times of the year is important. Most radical solutions such as minimum tillage and conservation tillage aim to have some degree of vegetation cover throughout the year, and therefore drill the new crop through the remnants of the old thus avoiding the bare ground inherent in tillage systems involving the plough.

Large areas of the same crop give rise to the risk of runoff at the same time. Thus the breakup of large fields into strips of different crops can reduce the risk. Valley-bottom zones of concentrated flow may be grassed (grass waterways) to prevent erosion. Buffer strips of grass are widely used around arable fields in order to reduce runoff volumes and loss of soil from fields. Evans and Boardman show how return to grass of a small area interrupts valley-bottom runoff from large areas of winter cereals thus preventing flooding of houses.^[64]

The desire to reduce slope gradients has traditionally been addressed by the construction of terraces. An added advantage is that a terrace allows for cultivation of slopes that were too steep for agriculture. Terrace systems are known from the Middle Bronze Age on Crete^[65] and from the Incas of Peru. Many systems around the Mediterranean are abandoned and erosion associated with their post-abandonment state has been much researched.^[66] Maintenance of terraces is therefore vital if they are to prevent erosion (Fig. 10).

Fig. 10 (A) Old abandoned terraces and rebuilt terraces, Mallorca, Spain; (B) abandoned terraces, central Corsica, France; and (C) abandoned and degraded terraces, Eritrea.

Fig. 11 Mitigation measures: grass buffers along field edges, the Melsterbeek catchment, Flanders, Belgium (Karel Vandaele, Samenwerking Land & Water).

It is doubtful if any one conservation technique will be effective on its own. Most successful schemes involve several approaches. For example, the Melsterbeek Catchment soil and water conservation scheme in Flanders use grass waterways, buffer strips, and retention ponds (Fig. 11). Successful schemes, such as this, must involve the local population of land owners and managers which generally requires financial support and technical assistance.^[67]

In the Palouse wheat growing area of Washington State, high erosion rates have persisted for over a 100 years and are particularly associated with the practice of summer fallow. The costs of reducing erosion by conservation practices are well illustrated:

Applying various measures of conservation treatment to the land will affect the economy of the basin. But erosion rates can be reduced by 40% in the low and high precipitation zones and 60% in the intermediate precipitation zone—without decreasing farm income. The erosion rate can be reduced 80% through maximum levels of conservation practices and retirement of 35,000 acres of steep, erodible land. Achieving this level of reduction would cost more than \$29 million in reduced productivity and increased operating costs.^[68]

Soil erosion is often best addressed in a wide framework of natural resource improvements. The issue of sustaining the livelihoods of the farmers as well as introducing conservation measures is critical. Examples of successful approaches from West Africa, New Zealand, Southern Brazil, northwest India, northern Cameroon, and Kenya are discussed by El Swaify.^[69] There is also the well-known case of the Machakos District, Kenya.^[70] Hudson discusses reasons for failure of soil conservation projects.^[71]

Previously quoted extremely high erosion rates for the Loess Plateau, China, and associated high sediment yields

for the Yellow River, appear to have been substantially reduced. Water–soil conservation practices are credited with 40% reduction in sediment loads, sediment trapping by major reservoirs with 30% and most of the remaining is due to precipitation decrease.^[72]

CONCLUSION

The assessment of erosion is necessary in order to understand the scale and extent of the problem. Many assessment methods have been used including experimental plots, sediment yield in rivers, field monitoring, remote sensing, Cesium-137, historical analysis, expert opinion, and modeling. All have advantages and disadvantages and may not be appropriate for particular circumstances. Assessment will include an evaluation of the type of erosion processes and their relative importance. The design of mitigation measures will depend on the outcome of the assessment. Mitigation measures must take into account the driving forces of erosion particularly its socioeconomic context and the need to support local peoples in recommending appropriate solutions.

Erosion: Carbon Dioxide

Pierre A. Jacinthe

Indiana University—Purdue University Indianapolis, Indianapolis, Indiana, U.S.A.

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Sizable amounts of carbon dioxide can be produced as a result of soil organic carbon mobilization by water erosion. Water erosion could elicit profound disturbances in the plant–soil–atmosphere segment of the global carbon cycle through a cascading process involving nutrient depletion, decreased biomass production, and the alteration of radiative and thermal properties of soils.

INTRODUCTION

The projected warming of global climate and the degradation of land resources by erosion are among the most pressing environmental challenges of the modern era. The warming trend in the world's climate is linked to the accumulation of radiatively active gases [carbon dioxide (CO_2), nitrous oxide, and methane (CH_4)] in the atmosphere.^[1] Atmospheric CO_2 concentration has been increasing at a rate of 3.2 Pg C yr^{-1} ($1 \text{ Pg} = 10^{15} \text{ g}$),^[2] which, if maintained, could profoundly alter the chemical composition and the energy balance of the earth's atmosphere. Although fossil fuel burning is the primary contributor to the atmospheric CO_2 buildup, it is estimated that agriculture and land use change contributed 25% of total anthropogenic emissions of CO_2 .^[3] In soils, the evolution of CO_2 occurs through soil respiration which includes root respiration and the microbial decomposition of crop residues and soil humus.

The soil organic carbon (SOC) content is positively related to structural stability and negatively related to the susceptibility of soils to erosion.^[4] Cultivation reduces the stability of aggregates,^[4] thereby increasing the erodibility of soils. The effect of SOC on susceptibility to erosion is best exemplified by the use of SOC content in determining the soil erodibility factor (K) in the universal soil loss equation.^[5] Worldwide, an estimated 1.11×10^9 ha of land are affected by water erosion,^[6] resulting in the annual transport of $20\text{--}25 \times 10^9$ Mg of sediment to rivers and oceans.^[7] While much is known about the protective role of SOC against soil erosion, information is limited regarding the fate of SOC mobilized by erosion. In this entry, we deliberate that water erosion, as a mechanism for SOC removal, has a profound effect on the global CO_2 budget, and we present an approach to assess erosion-induced CO_2 emission into the atmosphere.

ERODED SOC: STATE OF THE KNOWLEDGE

Water erosion involves the detachment of soil aggregates, the release of aggregate-protected SOC, and the translocation and deposition of detached soil particles. Globally, the estimates of SOC displaced in terrestrial ecosystems by water erosion are in the order of 57 Pg C yr^{-1} .^[8] There is considerable uncertainty regarding the fate of the eroded SOC, however. The Intergovernmental Panel on Climate Change echoed this uncertainty in its handbook for conducting national greenhouse gas inventory by stating that the net effect of erosion on CO_2 evolution is unclear at the time.^[2]

The fate of SOC mobilized by erosion can include redistribution, long-term storage in aquatic and terrestrial systems, and mineralization during transport and deposition leading to emission of CO_2 (the production of CH_4 is possible depending on the oxidation status). During transport, detached soil particles are hydrodynamically sorted and redistributed over the eroding landscape as determined by flow condition, surface roughness, particle size, and geomorphology. Between 80% and 90% of the total soil mass mobilized by water erosion remains near the site of erosion.^[9] A fraction of the eroded SOC is exported to streams, rivers, and lakes. Several publications have documented the magnitude of these exports which are in the order of $0.6\text{--}0.8 \text{ Pg C yr}^{-1}$.^[10,11]

Eroded SOC in runoff is also retained in the low-lying portions of the eroding landscape, but the fate of SOC entrapped in these terrestrial deposits is also not fully understood. On the premise that the decomposition process may be oxygen constrained, it has been suggested that entrapment of eroded SOC in terrestrial deposits can be a mechanism for carbon (C) sequestration.^[12,13] It is estimated that a sequestration of $0.6\text{--}1.5 \text{ Pg C yr}^{-1}$ may be possible via this mechanism.^[13]

Eroded soil materials typically contain twice as much (or more) C than the average topsoil.^[12] In addition, these

materials are enriched in labile C.^[14] Given the propensity of these SOC fractions to be associated with the lighter and most erosion-prone soil particles, the mineralization of eroded C during transport and deposition is a reasonable expectation. A study comparing CPMAS ¹³C-nuclear magnetic resonance spectrometry data of eroded and deposited soil samples indicated that 70% of SOC in eroded soil could be decomposed during transport and deposition.^[15] A review suggests a lower (20%) mineralization rate.^[8]

The abovementioned information clearly underscores the need for better quantitative assessments of the various fates of eroded SOC. Of particular interest is an assessment of water erosion's contribution to atmospheric CO₂. At that time, there is almost no experimental data to support such an evaluation. However, an indirect determination of CO₂ production during transport and deposition of eroded SOC is possible using literature data pertaining to the other pathways identified above.

ASSESSMENT OF EROSION-INDUCED CO₂ FLUXES FROM AVAILABLE DATA

Conceptual Framework and Description of the Mass Balance Approach

In order to estimate CO₂ production during transport and deposition of eroded SOC, a mass balance approach,

described in Fig. 1, is proposed. This approach assumes a steady-state equilibrium with respect to SOC content. Augmentation of the initial pool of SOC via humification of crop residues compensates for SOC losses, which include soil respiration, leaching, and SOC translocation with runoff waters. It follows that:

$$C_0 + h.C_A = C_t + S_R + E \quad (1)$$

$$S_R = k.C_t \quad (2)$$

$$E = L_C + S_W + E_W + S_L + E_L \quad (3)$$

$$E_L = (C_0 - C_t)/t + h.C_A - k.C_t - (L_C + S_W + E_W + S_L) \quad (4)$$

where C_0 is the initial SOC stocks, h is the humification rate, C_A is the annual residue addition, C_t is the SOC stocks after t years, S_R is the annual SOC mineralization, k is the coefficient of SOC mineralization, L_C is the leaching loss of SOC, S_W is the terrestrial C delivered to lakes and oceans, E_W is CO₂ evasion from aquatic systems (lakes, rivers, and streams), S_L is the C storage in terrestrial deposits, and E_L is the mineralization and CO₂ evolution during transport and deposition of eroded SOC. The coefficients h and k are in units of yr^{-1} , C_0 and C_t are in g C m^{-2} , and the other parameters are in units of $\text{g C m}^{-2} \text{yr}^{-1}$.

Using Eq. 4, CO₂ evolution during transport and deposition of eroded SOC (E_L) can be computed. Values

Fig. 1 A conceptual mass balance model of SOC evolution in soils.

SOC might go unnoticed for some time. Removal of SOC via sheet erosion could be particularly difficult to detect in the short-term, hence a possible, dismissal of water erosion as an important mechanism for SOC loss.^[26] However, field study data support the view that erosion is a significant contributor to SOC decline and sometimes contributes more to SOC depletion than soil respiration.^[27,28]

If the data in Table 2 are extrapolated to the global cropland (1.5×10^9 ha),^[29] erosion-induced global CO₂ fluxes to the atmosphere ranging between 0.12 and 0.55 PgCyr⁻¹ can be computed. These fluxes could represent up to one-third of the annual CO₂ emission (1.6 PgCyr^{-1}) due to deforestation and land use change in the tropics.^[8]

CONCLUSION

The information presented in this entry supports our contention that sizable amounts of CO₂ can be produced as a result of SOC mobilization by water erosion. Moreover, water erosion could elicit profound disturbances in the plant–soil–atmosphere segment of the global C cycle through a cascading process involving nutrient depletion, decreased biomass production, and the alteration of radiative and thermal properties of soils. The strong control of temperature on CO₂ emission^[30] and the higher temperature usually recorded in eroded soils^[31] also indicate a shortened residence time of photosynthetically fixed C in the soil system. Although many of the effects are to be evaluated experimentally, available information suggests a positive feedback of water erosion on atmospheric CO₂ and climate warming.

Abstract

Erosion is the greatest threat to agricultural sustainability. Irrigation-induced erosion and rainfall-induced erosion result from the same physical and chemical processes. However, the processes come together and interact very differently in each case. This entry presents methods of combatting irrigation-induced erosion.

INTRODUCTION

Erosion is the greatest threat to agricultural sustainability. Most irrigation is on fragile arid soils that have enormous crop yield potential when irrigated. However, the yield potential is easily lost if the thin veneer of “topsoil” is eroded.^[1] Erosion prevention on irrigated land is arguably more important than on rain-fed land. Yields from irrigated land are more than double than those from non-irrigated land, with nearly triple the crop value per hectare.^[2] In addition, runoff and irrigation return flows (necessary in many surface irrigation schemes) deliver sediment; human, animal, and plant pathogens; and nutrients and pesticides to downstream fields and riparian waters. These pollutants accumulate in runoff primarily as a result of erosion.

IRRIGATION'S UNIQUE EROSION CHARACTERISTICS

Irrigation-induced erosion and rainfall-induced erosion result from the same physical and chemical processes. However, the processes come together and interact very differently in each case.^[2–4] The magnitude of the differences depends on the type of irrigation system and on soil and water properties. (See the entry *Irrigation: Erosion*, p. 1261.) Briefly, the most important differences stem from soil and water chemistry, wetting rate, water application and infiltration patterns, and, for surface irrigation, the absence of water drop impact. These factors are the basis for many erosion control practices unique to irrigation.^[4–7] Since 1990, advances in irrigation erosion control have resulted from the improved understanding of water quality and antecedent soil condition effects on erosion and from the development of polyacrylamide (PAM) use.

The key to controlling erosion is controlling runoff. Runoff is controlled in two ways. It is minimized by scheduling irrigation to meet, but not exceed, crop water and salt leaching requirements (i.e., avoid over-irrigation), and it is managed by using application rates during each scheduled irrigation that minimize runoff and erosion for that event. Systems should be designed and operated to minimize over-irrigating of some areas in order to adequately irrigate others. In furrow irrigation, this is accomplished by reducing the length of furrows, managing inflow rates and advance times, and where possible, cutting back inflow rates once runoff begins or through use of surge irrigation (surge irrigation sometimes erodes near the inlet because of higher flows during initial pulsing of water). Sprinkler systems can reduce runoff with variable rate emitters that match application rates to soil infiltration rates at specific field locations.

Erosion reduction from improved scheduling and application management is usually proportional to runoff reduction. Reducing overapplication also reduces pumping costs and losses of applied nutrients and agrichemicals. In surface irrigation systems, where 20–40% runoff is often required to achieve field application uniformity, erosion remediation can be integrated into water supply enhancement by pumping sediment-laden drain water back onto fields. This does not prevent erosion but does replace most of the eroded soil along with the saved water for the pump-back cost.

METHODS OF CONTROL

Conversion to Sprinklers

One effective way to prevent irrigation-induced erosion is conversion from surface to sprinkler irrigation.

Again, the soil conservation benefit from conversion to sprinklers derives from and is proportional to the reduction of runoff. Sprinkler irrigation has higher technical, capital, energy, and infrastructure requirements than surface irrigation. Therefore, sprinklers are used only on a small fraction of global irrigated area, whereas nearly 60% of U.S. irrigated land uses sprinklers. Properly designed and managed sprinkler systems eliminate 100% of off-site sediment losses. However, with sprinklers, there is a tendency to extend irrigation to steeper slopes or otherwise more erosive lands. On steep land, when sprinkler systems are poorly designed or managed, erosion can occur.

Center pivots can cause erosion problems because of water running in wheel ruts, down steep slopes, or due to high application rates at outer reaches of the pivot,^[8] especially when using extendable booms and high volume end guns to reach corners. Erosion from high application areas, or where runoff concentrates, can be reduced using tillage, pitting, and mulching between rows to increase surface roughness storage and reduce runoff.^[9–11]

Soil Protection and Tillage

Many approaches developed to control rainfall-induced erosion can prevent irrigation-induced erosion, particularly under sprinklers, e.g., no-till and conservation tillage, which rely on crop residue to protect the soil surface. Despite typical erosion reductions >90%, often with increased yields,^[12] no-till and conservation tillage are rarely practiced by surface irrigators. Floating residue often migrates along and clogs irrigation furrows, washing out adjacent beds and furrows, while under-irrigating the blocked furrow. In basin flood irrigation, floating debris can interfere with water spreading, sometimes concentrating initial flows, eroding some areas, and burying emerging plants with sediment or debris. No-till farming with furrow irrigation is further complicated by crop rotations that require different row (and furrow) spacings each season.

Sojka et al.^[13] demonstrated 60% reduction in field sediment loss from furrow-irrigated potatoes that were paratilled (subsoiled) following planting. Slight yield increases and significant tuber grade improvements raised profitability under both furrow and sprinkler irrigation with paratilling.^[14] Because irrigation assures crop water availability, yield benefits from improved root development are not consistently seen with subsoiling in irrigated crops.^[15] Subsoiling is commonly practiced with sprinkler irrigation to enhance infiltration and decrease runoff, thereby reducing erosion. However, farmers are cautious about subsoiling furrow-irrigated crops because of the potential for irregular water flows in subsurface cracks to interfere with irrigation uniformity. Field preparation or land forming practices that

reduce water application uniformity, or increase runoff, are avoided by irrigators.

Placing mulch or growing sod in irrigated furrows reduces erosion. Sod nearly eliminated runoff sediment.^[16] Straw mulching reduced sediment loss from 52% to 71%.^[17–20] Drawbacks of these techniques relate to the management of sodded furrows, the added operations and equipment needed to place straw, and debris migrating along and clogging mulched furrows.

Site Modification

Various “engineering” approaches have been used to reduce field sediment losses from surface irrigation. The most common is use of settling basins. Large quiescent pools to facilitate particulate settling from runoff collected from fields up to 20 hectares are fairly typical. Settling pond size depends upon the area served, rate and volume of runoff, sediment concentrations expected, and particle-size distribution. Small settling basins along the bottom of surface-irrigated fields, serving a few rows per basin, are sometimes easier to manage at season’s end, when trapped sediment spread back onto the field using farm equipment. Big ponds require large-scale equipment for construction, cleaning, and soil redistribution. For medium-textured soils, about 60% of suspended mass entering settling ponds is retained. The non-retained soil is of the clay size range.^[21] Since clay carries most of sediment’s adsorbed nutrient and chemical load, failure of ponds to retain clay impedes the retention of agricultural chemical pollutants despite the high percentage of sediment mass captured. Furthermore, effectiveness declines as ponds fill with sediment, reducing water residence time. Another variation on ponds is the installation of buried drains and standpipes to regulate water level in tail ditches.^[22] The standpipes force ponding and prevent gradual concaving of field tail ends. They do not, however, prevent loss into the drain of sediment entrained in runoff from upper field reaches.

Altering canopy configuration can reduce erosion. Sojka et al.^[23] halved field sediment loss using narrow or twin row plantings. Water ran between closely placed furrows, reducing irrigation duration (and runoff) and allowing root systems and canopy debris to reduce soil detachment in the furrow. Filter strip crops drilled at right angles into the final 3–6 m of furrow-irrigated row crops also remove entrained sediments from runoff^[6] but do not prevent sediment migration from field inlet to tail end. Because filter strip management is a compromise between two crops, yield from the strips is typically half that expected for either crop alone.

Water Properties

Both the physical and chemical properties of irrigation water affect erosion. Erosion is greatly reduced by reducing

sprinkler droplet size or energy^[24,25] or by reducing stream flow in furrows.^[26] These physical changes require adjustments in application timing, furrow lengths, and irrigation durations to properly match water application constraints with crop water needs.

Water electrolyte chemistry greatly affects the erosiveness of irrigation water.^[27–30] High sodium adsorption ratio (SAR) and low electrical conductivity (EC) contribute to soil aggregate detachment, disruption, and dispersion of fine primary soil particles in runoff. The effect of low EC and high SAR is synergistic. Increasing electrolyte concentration with a calcium source lowers SAR, shrinks the ionic diffuse double layer around charged soil particles, and prevents dispersion, thereby maintaining aggregate stability and resisting erosion. The conjunctive use of waters from different sources or the addition of calcium can raise EC and/or lower SAR to reduce erosion potential and improve infiltration by stabilizing surface soil structure.

Adding large polymeric compounds to irrigation water is an effective erosion prevention technology.^[31–33] These compounds, when delivered in dilute concentrations (typically 1–10 ppm) by the irrigation stream, increase aggregate stability and interaggregate cohesion as water infiltrates. The erosion reduction of 95% is typical for the application of 1–2 kg/ha per treated irrigation. Adoption has been the greatest for furrow irrigation erosion reduction, but interest in extending the technology to sprinklers is growing as much to improve infiltration uniformity as to reduce erosion.^[34–36] The most successful class of polymers has been anionic PAM, allowing safe, easy, and effective erosion prevention for seasonal application rates of 3–5 kg/ha^{−1}, or under \$35/ha^{−1} per season.^[37]

Erosion: Crop Yield

Michael Stocking

School of Developmental Studies, University of East Anglia, Norwich, U.K.

Abstract

Erosion-induced loss in soil productivity is one of the major threats to global food and economic security, especially to resource-poor farmers in the tropics. It not only diminishes the quality of soil resources but also makes gaining a livelihood from the land increasingly difficult. By reducing the productivity of the soil, it affects outputs such as crop yields derived from the renewable natural resource systems of the biosphere. By affecting the net primary production of vegetation, erosion is the driver for a number of critical environmental, economic, and social issues in the developing and developed countries alike.

INTRODUCTION

In tropical and subtropical developing countries, the majority of people are dependent on low external input agriculture. Directly they rely on the inherent quality of soil resources. Because of high-intensity (erosive) rainfall, susceptible (erodible) soils, and sensitive ecological balances, the processes of erosion are significantly accelerated in the tropics compared to temperate areas. Their impacts, in terms of both yields lost and livelihoods jeopardized, are considerably magnified. In the developed countries, usually temperate to subtropical, soil erosion is also a critical concern. However, fewer people are directly dependent on the soil, and the processes can be addressed more easily through the application of technology and economic resources. Impacts may be mitigated through, e.g., the application of fertilizer or using irrigation. Off-site effects such as siltation of reservoirs can be offset by available, albeit costly, remedial measures. Nevertheless, many commentators (e.g., see Pimentel et al.^[1]) find the prevalence of soil erosion and associated losses in crop yield totally unacceptable and unsustainable, and they predict environmental catastrophe. It should be noted, however, that the evidence for erosion and its widespread impact is by no means unchallenged.^[2,3]

Soil quality and soil resilience, soil fertility and plant nutrients, conservation and rehabilitation, soil management, yield output and environmental risk, and farming livelihoods are just a few of the problematic implications of soil erosion and declining crop yields. Arguably, erosion affects not only the economics of production, but also the stability, security, and life support of society.

“HOT SPOTS” FOR SOIL EROSION AND ITS IMPACT

Largely to identify those parts of the world with especially severe impacts of soil erosion, the concept of hot spots of land degradation was devised in 1995 by an expert meeting at the International Food Policy Research Institute in Washington, D.C.^[4] It is a useful concept in that erosion can then be related to processes such as deforestation, inappropriate agricultural mechanization, and building of engineering structures, to identify not only the severe status of soil erosion but also the primary causative agents and the effects on human society. An example of hot spots for Africa is given in [Table 1](#). These are places where expert opinion has identified soil erosion as posing a significant threat to food security for large numbers of people. Policy interventions should be targeted at such situations in order to address the developmental needs of the poorest people in the most vulnerable biophysical environments.

SOIL EROSION-PRODUCTIVITY RELATIONSHIPS

Unambiguously ascribing declining yields to the effects of the processes of soil erosion is difficult. Yields may decline for various reasons, such as excessive off-take of nutrients in crops without replenishment, pests and diseases, weed infestations, and increasing prevalence of drought because of global climate change. Soil factors, some associated with erosion, may also be responsible, such as reduction in effective rooting depth; decrease in available water capacity; decline in soil organic carbon; salinity and sodicity; and other chemical changes causing

Table 1 Hot spots for soil erosion, land degradation, and crop yields in Africa.

Nutrient depletion	Water and wind erosion	Vegetation degradation	Constraints to yield increase
Semiarid croplands of Burkina Faso and Senegal (leading to outmigration)	Subhumid SE Nigeria on sandy soils Wind erosion in Sahel	Arid and semiarid rangeland devegetation (e.g., Ciskei), particularly near water sources	Lack of suitable technology for crops grown in areas less than 300-mm rainfall in North Africa
Large areas under transition to short fallow or permanent cropping	Mechanization in North Africa causing water and wind erosion	Devegetation due to intensive collection of wood fuel (around cities)	Unsustainability of annual crops in humid lowlands of West Africa
Reduction of silt deposits in Nile Delta following construction of Aswan High Dam	Mechanization with inappropriate plowing techniques (e.g., transition zone of West Africa)	Devegetation due to overstocking (e.g., Morocco and Tunisia) Reduced yields due to <i>Imperata</i> and <i>Chromolaena</i> infestations in degraded soils	Densely populated highlands in Rwanda, Burundi, and Kenya—no obvious source of production increase

Source: From Scherr & Yadav^[4] and Tengberg & Stocking.^[5]

toxicity by aluminum, heavy metals, or acidification generally. Behind all these, as an associated factor, is one form of soil degradation or another, including the most common type, soil erosion by water. Indeed, such is the complexity of interrelated factors that soil erosion and declining biomass production will accompany almost any negative environmental change. Thus, at the least serious end of the scale of impact, the conversion of dryland savannah to continuous soybean will necessarily provoke accelerated soil erosion because of the soil

disturbance and reduced vegetation cover. The legume may contribute some replenishment of soil nitrogen, and the remaining roots and stover may contribute some organic matter. But eventually that erosion must have a net deleterious effect on production because of reduced topsoil thickness, loss of colloids, and a lowered capacity to hold plant-available water. However, at a cost, sustainable agricultural production systems can accommodate these changes, and production can effectively be continued indefinitely through the application of sufficient

resources and skills. At the most serious end of the scale, “badlands” (the combinations of extremely serious erosion, with gullies, rills, pipes, and other phenomena typical of abused semiarid sites) have no vegetation whatsoever. In both cases, is it soil erosion that causes declining vegetation?—yes and no. A diminished soil quality brought about by erosion must affect plant processes of production and reproduction though the effect may be masked through technology and inputs. Equally, reduced vegetation brings about more soil erosion. However, completely denuded landscapes are rare. The eroded soil is deposited elsewhere, bringing with it nutrients, organic matter, and water, as well as enhanced production opportunities for local people. South Asia has many examples of “sediment harvesting,” such as the *nullah plugs* in India. So, in the discussion of erosion–productivity relationships, it must always be recognized that: 1) the relations are complex and direct cause–effect conclusions should only be entertained cautiously; and 2) a deleterious effect in one part of the landscape may bring benefits elsewhere.

With these caveats in mind, it is possible to define the relationships between erosion and yield. This is usually done experimentally on runoff plots, where measured soil losses are related not only to the factors of erosion but also to the existing and future yields of crops (see Olson et al.^[6] for other methods to study the erosion–productivity relationship). In the mid-1980s, the United Nations’ Food and Agriculture Organization (FAO) developed an experimental design to investigate erosion–productivity relationships.^[8] By attempting to hold all factors constant other than prior degree of erosion and crop yields, the small plots were allowed to erode by natural rainfall to different degrees and then planted to a standard crop to measure the impact on plant production. At the same time, the explanation for the relationships between erosion and productivity was determined through analyzing the change in *in situ* soil variables assumed to have been caused by the erosion. The database has been used to construct scenarios of food insecurity if erosion were allowed to continue (e.g., see Tengberg and Stocking^[5]).

There is good evidence that yield decline with erosion follows a curvilinear, negatively exponential form (Fig. 1). After a sharp initial decline from a status of high productivity, there follow successive stages of decreasing further impact. While this general form of the relationship may not

hold true for all conditions, the implications for attempts to maintain food security are clear. It is exceedingly difficult to bring back severely degraded land into useful, or even economic production. Slightly degraded land is relatively easily brought back into use, and the returns on an investment in conservation are always better if erosion has not progressed beyond a 50% drop in yield levels. Erosion–yield–time scenarios have been addressed by the FAO, and Table 2 summarizes overall results in the form of years to reach a threshold yield level for maize of 1000 kg ha⁻¹ for some typical soil orders (in the FAO classification). The differences between a resilient soil such as a Nitisol (clay-rich, common in basic rocks of highlands) and extremely sensitive soils such as Ferralsols and Acrisols (common in acid humid tropical rainforests) are stark.

CONCLUSION

Both soil erosion and its effect on crop yield vary in their extent and seriousness. Tropical, developing countries have the most critical conditions, through a combination of environmental, social, and economic factors. Scientists are recognizing that some of the crisis statements of the past owed more to rhetoric than to reality. However, policies are urgently needed to combat the hot spots of soil erosion, so that local communities may continue to rely on their soil resources in the future. International initiatives, such as those through the Convention to Combat Desertification, are starting to address the complex issues involved. But much more needs to be done in matching technologies to local conditions, addressing the link between erosion and yields, showing how local and global objectives such as carbon sequestration are related to soil erosion, and understanding the associated economic and social impacts of allowing erosion to continue. The challenge is immense.

Erosion: Disturbed Lands

William J. Elliot

U.S. Department of Agriculture—Forestry Service (USDA-FS), Moscow, Idaho, U.S.A.

Abstract

Disturbed lands include construction sites, mine sites, roads, forests that have been disturbed by fire or other operations, and military maneuver sites. Erosion rates on disturbed lands are highly dependent upon factors such as climate conditions immediately following the disturbance, the type and degree of disturbance, local topography, and the natural vegetation regeneration or mitigation measures. Soil properties also influence erosion rates but tend to be overshadowed by the other factors. A high degree of variability is associated with each of these factors; thus, the erosion rates resulting from disturbances are highly variable.

CLIMATE AND HYDROLOGY

Vegetation regeneration on disturbed sites depends upon precipitation. Too little precipitation means that the site takes longer to regenerate, whereas too much precipitation will likely lead to excessive soil erosion that may also hinder revegetation. However, high levels of low-intensity precipitation will generally result in rapid regeneration and minimal erosion risk.

DISTURBANCES

In the absence of disturbances, land surfaces are often covered in forests or rangelands. Disturbances can accelerate erosion rates as much as one thousand times more quickly than on undisturbed sites. Disturbances may be natural, such as major storm or flood events and fire (Fig. 1), or human caused, such as roads (Fig. 1), construction (Fig. 2), forestry, or mining (Fig. 3). Erosion rates of undisturbed rangelands and forests are low (Table 1). However, occasional natural disturbances are part of the ecosystem, and any increased erosion rates from human disturbances should be compared with both the undisturbed and naturally disturbed erosion rates.

Fire and Water Repellency

Fire may be natural or intentional. Generally, natural or “wild” fires tend to be more severe because the forest or range must be in a drier condition for a wildfire to initiate. Intentional or “prescribed” fires are applied in early summer or after autumn rains have begun, to minimize the amount of litter that is burned, while reducing the amount of aboveground woody debris. Managers use fire to provide improved grazing for livestock and wildlife and to try to improve forest or range health. Fires are

commonly used in forests following a harvesting operation to reduce the amount of remaining woody material or to improve the health of the forest and the success of regeneration. Such practices—when used with a suitable undisturbed buffer between the fire and a stream channel—can minimize upland erosion and sediment delivery risks.

Fire may cause soils to become water repellent. Water repellency is caused by the condensation of hydrocarbons on soil particles and aggregates when organic material is combusted. It can reduce the hydraulic conductivity of soil from 30–80 to 15–40 mm hr⁻¹ in forests.^[6] Rangelands tend to be less susceptible to repellent conditions following fire, although some range shrub communities as well as some forest soils can be naturally repellent. The reduced hydraulic conductivity values associated with repellency may be greater than rainfall intensities or snowmelt rates in the year following the fire. The chemicals causing repellency are water soluble, and repellent soils tend to recover to prefire conditions within 3 or 4 years, if there is sufficient precipitation. If there is a major storm or runoff event that occurs when soils are highly repellent, erosion rates can be large (20–100 Mg ha⁻¹), but if storms are of low to average intensity, erosion rates are likely to be moderate, typically under 10 Mg ha⁻¹. Water repellency can be reduced through tillage, but burying remaining surface residue tends to offset any benefits of reduced repellency.

Anthropogenic Soil Disturbances

Anthropogenic or human-caused disturbances can cause minor changes in the landscape, such as a road (Fig. 1), a footpath, a logging skid trail, or off-road vehicle tracks from recreational or military uses. Human activities can

Fig. 1 Two disturbances that may cause increased erosion are wildfire, and roads. This photograph was taken several weeks after forest fires ravaged Western Montana in 2000.

also cause major landscape disturbances, such as a construction site (Fig. 2) or a surface mine spoil heap (Fig. 3). The same general erosion principles, however, can be applied to all disturbances. The main impacts of these disturbances are reduced live vegetation, loss of surface cover by decaying vegetation, and soil compaction. In addition, roads and mining may expose soils low in organic matter, and high in rock content or undesirable trace elements. These conditions are not conducive to vegetation regeneration, further aggravating long-term erosion risks.

Runoff rates are much higher on most disturbed areas than undisturbed areas. On roads, for example, the hydraulic conductivity can be reduced to near zero (under 0.1 mm hr^{-1}).^[7] Bulk densities are generally increased from under 1.0 Mg m^{-3} in forests and range to over 1.4 Mg m^{-3} on roads. Compaction reduces the water-holding capacity of the soil, which increases runoff and erosion. The increased runoff reduces the amount of water held in storage for the summer, subsequently reducing vegetation regeneration rates. Large

Fig. 2 A construction site exposing large areas to soil erosion until vegetation can be re-established. Silt fences and straw bales have been installed to reduce sediment delivery.

Fig. 3 A surface mine spoil heap many years after mining in northern Idaho. The lack of vegetation increases susceptibility to erosion, but the large rock content reduces actual erosion risks.

rocks (Fig. 3) and acidic soils are common to many mining sites. The rocky surface tends to reduce runoff and erosion but increases the difficulty in establishing vegetation.

In many cases, it is not possible to prevent erosion on a road, a highly disturbed construction site, or mining site. In these cases, managers frequently incorporate practices to reduce off-site erosion using various sediment control techniques such as silt fences, straw bales (Fig. 2), and sediment basins. Vegetated buffer strips are

Table 1 Typical erosion rates in forests, rangelands, and disturbed sites.

Condition	Estimated area in the United States (millions of hectares)	Typical erosion rate (Mg ha^{-1})
Undisturbed forests	200	0.1
Undisturbed rangelands	200	1
Harvested forests	4	1
Conservation agriculture	80	5
Forests after low-severity wildfire	1	10
Overgrazed rangelands	50	10
Rangelands after fire	10	10
Forest roads	3	20
Intensive agriculture	80	20
Surface mines in need of reclamation	0.02	50
Forests after high-severity wildfire	1	100
Construction sites	—	100

also commonly used to reduce the amount of runoff and sediment leaving such sites.

Reclamation of highly disturbed sites generally involves techniques such as subsoiling, mulching, and fertilizing to improve soil productivity. Vegetation is then established that will likely provide rapid surface cover until natural cover returns. Once the site is revegetated, erosion risk is minimal.

VARIABILITY

Soil erosion varies greatly with time and in space on disturbed sites. Soil properties and subsurface geologic properties vary along all hillslopes. Roads, skid trails, and other trails can be quite different than the surrounding areas in hydrology and erodibility. Spatial variation is very high following both prescribed and wildfire, leading to major variability in the erosion risk that may follow.^[8] Seasonal variability in climate can have major impacts on erosion rates. Large soil erosion events tend to occur only from major runoff events, or when large runoff events occur on areas that have been disturbed. "Average annual erosion" has little meaning under conditions dominated by temporal variability.

Following disturbance, hydrologic recovery also varies greatly. North-facing slopes may recover faster than south-facing slopes. Topsoils recover faster than subsoils or mine spoil. A dry year following a disturbance may result in little water repellent recovery, a moderate year significant recovery, but a wet year may cause catastrophic flooding and erosion. Large events could disturb a watershed for decades, while stream channels and upland surfaces return to hydrologic stability. Under these conditions, it may be more appropriate to consider the probability of a given amount of erosion occurring rather than an average value.

Because of the spatial variability following disturbances, a given landscape will have sites of net runoff and sediment generation and sites of net infiltration and deposition. The distribution and occurrence of these sites will determine the net landscape response to an erosion event. On landscapes with a few scattered areas of severe disturbance, there may be no net runoff and erosion. This is particularly true with roads, where sediment delivery is minimal if the roads are located a reasonable distance from streams. Only severe storm events that exceed the infiltration capacity of the entire hillslope will cause any net off-site sedimentation.

SURFACE COVER

The amount and distribution of surface cover will determine the erosion rate following most disturbances. Surface cover is generally decomposing vegetation but can also include animal waste, gravel, rocks, and

fabricated materials like erosion control blankets. As surface cover increases from zero to 100%, erosion rates will drop by 99% or more. With fires and grazing, natural spatial variability is extremely high, whereas with military activities, forest harvesting, and roads, the distribution of disturbance on the landscape may be more predictable and more easily managed. Increasing surface cover with vegetation regeneration, mulch, or erosion control fabrics is usually the most effective mitigation method for disturbed sites, although costs can be high.

EROSION PREDICTION

Erosion on disturbed sites can be predicted with both empirical models [such as the Universal Soil Loss Equation (USLE)] and physically based models [such as the Water Erosion Prediction Project (WEPP) model].^[9] Factors have been developed for construction sites for the USLE,^[10] and that technology has been incorporated into many predictive software programs. Interfaces for predicting erosion following fire and forest roads have been developed for the WEPP model,^[11] as have input soil files for construction sites.^[12] When using any of these technologies, model users must carefully consider the period of time that the site is disturbed, the chosen mitigation practices, and how fast the site is revegetated.

Erosion: Effects on Human Life

Neroli Pedro Cogo

Renato Levien

Federal University of Rio Grande do Sul, Porto Alegre, Brazil

Abstract

Soil erosion is a problem associated with human life on earth. It threatens soil productivity, food production, the environment, and quality of life. Fortunately, erosion-induced problems have been well recognized and sound control measures have been developed. To maintain the natural resources and environment for a sustainable civilization, soil erosion from agricultural lands must be controlled.

INTRODUCTION

Soil is, and long will be, a vital resource and an essential medium for life on earth. Plants growing in the soil provide food for human and animal needs. However, because the rate of human-induced water and wind erosion can greatly exceed natural rates of soil formation and erosion,^[1,2] the soil may become depleted and severely affect crop production. Therefore, the soil must be considered a non-renewable natural resource to be protected and preserved for future generations. Maintaining soil productivity for sustainable food production is a challenge for farmers, agricultural and environmental professionals, and governments worldwide.

HISTORICAL EVIDENCE OF EROSIONAL EFFECTS

Decline of civilizations as a result of soil degradation (particularly soil erosion) is well documented.^[3–7] Soil degradation and civilization interact in both directions, meaning erosion-induced land degradation affects human lives, and human activities often enhance soil degradation.^[6]

Historically, three major human-induced erosion periods can be identified.^[7] The first period, between 1000 and 3000 years ago, occurred because of the excessive timber cutting and expanded cultivation. The second period, during the 19th and early 20th centuries, occurred in countries colonized by European immigrants. Through the establishment of an exportation type of agriculture, the immigrants forced the native population to move and to explore the more erodible, marginal lands, while holding the better lands for a marketing economy. The third period, beginning in the early 1920s and extending to the present day, occurred mainly in developing countries with a growing population pressure for more land and food production. This population growth forces farmers to develop new

lands, some good and some only marginal for agricultural production, and to adopt intensive, non-conserving cropping and management systems which cause spectacular levels of soil erosion.

The situation varies throughout the world. In many regions, the seriousness of the erosion problem has been recognized and effective erosion control measures adopted. In other regions, erosion is a major crop production impairment and continuously causes extensive sedimentation and water pollution problems.

HOW SOIL EROSION AFFECTS CROP PRODUCTIVITY AND HUMAN LIFE

The primary effect of soil erosion on crop productivity is a reduced yield (less kg/ha of grain, dry matter biomass, tubers, and fruits) that results from the removal of fertile topsoil and the contained nutrients. In a review paper, Langdale and Schrader^[8] prepared a table showing soil erosion–crop productivity relationships for soils in the Southeastern and Midwestern United States; some of their findings are detailed in [Table 1](#). Because it reduces animal feeds, erosion also results in a reduced livestock yield (less kg/ha of meat, milk, and wool). This means erosion affects both vegetal- and animal-originated food productions. In addition, products of erosion (e.g., soil particles, water-runoff, dissolved chemicals in the runoff-water, and chemicals adsorbed to the soil particles) may cause serious damage to the environment. Decreased food production and increased sedimentation and water pollution caused by soil erosion mean a diminished quality of life for humans.^[8–13]

Erosion affects crop yield through degradations in the soil's physical, chemical, and biological properties. Physical degradations caused by soil erosion are: 1) loss of plant-available water reserve and water storage capacity; 2) reduced rooting depth; 3) increased soil crusting; 4) reduced aggregate stability and soil tilth; 5) formation

Table 1 Examples of how soil erosion affected crop productivity.

Degree of erosion	Crop yield (kg/ha)				
	Corn	Soybeans	Cotton	Small grains	Forage
Southeastern United States					
Grenada silt loam (Glossic Fragiudalfs), 0–5% slope					
None	6,000	2,700	840	3,600	7,200
Eroded	5,300	2,000	784	3,100	6,700
Severe	4,400	1,600	672	2,700	6,000
Cecil sandy clay (Typic Hapludults), 2–10% slope					
Deposition (local alluvium)	6,200	—	—	—	—
Eroded	5,800	2,100–3,100	1,389	2,400	17,400
Severe	1,900	1,500–2,400	866	1,600	13,700
Midwestern United States					
Marshall silty clay loam (Typic Hapludolls), 2.5–6.0% slope					
None	—	—	—	—	—
Slight	6,700	2,800	—	2,200	9,000
Moderate	6,200	2,600	—	2,000	8,500
Ida silt loam (Typic Udorthents), 6.0–9.0% slope					
None	—	—	—	—	—
Moderate	5,200	2,200	—	2,100	6,900
Severe	4,300	1,700	—	1,700	5,800

Source: From Langdale & Schrader.^[8]

of rills and gullies that fragmentize the land; and 6) exposure of a subsurface soil layer that is inadequate for plant growth. Chemical degradations from erosion include: 1) reduced plant nutrients; 2) reduced cation-exchange capacity from the removal of fine soil particles and associated organic matter; and 3) increased toxicity of aluminum and manganese, and soil acidity owing to the exposure of a less-favorable subsurface soil layer. Biological factors affected by erosion include loss of carbon in the biomass and reduced micro- and macrofauna activity.

Production costs on degraded lands are also elevated because of increased fertilizer needs to offset soil nutrient loss, machine power to till and plant more compacted subsoil, and additional seed cost in replanting stand loss from soil crusting and seeds washing off. These effects also cause an increase in machine wear, fuel consumption, time, and labor, and, consequently, increased production cost.

The effects of soil erosion on crop productivity and the environment may be strongly felt by society as a whole, but it essentially affects the human's quality of life (Fig. 1). In addition to rural society stricken by reduced crop yield and

Fig. 1 A family from Rio Grande do Sul State, Brazil, whose farm suffers from severe soil erosion.

increased production costs, urban society also suffers from higher cost for food and reduced environmental quality. There is evidence of this in developing countries with extreme cases of erosion. In these instances, farmers cannot maintain a basic subsistence level, so they abandon their land, move to the cities, and cause what is known as rural exodus. The society also bears the costs of restoring reservoir and river capacities and cleaning chemically polluted surface waters caused by eroded sediments.

AWARENESS OF SOIL EROSION: CROP PRODUCTIVITY RELATIONSHIP

Despite historical evidence that human-induced erosion has occurred worldwide wherever land has been cultivated, awareness of the erosion-induced problem developed slowly. The study of soil erosion as a science started only approximately 100 years ago, between 1877 and 1895, by German soil scientist Ewald Wollny.^[14]

It is difficult to assess the cost of erosion-induced damages to society in terms of loss of food production, water storage and quality, and quality of life. This may partly explain why soil erosion, even though universally recognized as the greatest threat to food security, environmental quality, and human well-being, is continuously uncontrolled in many parts of the world. If soil erosion and crop productivity relationships were better understood, people might be more willing to accept erosion control measures. The society could determine whether erosion control regulations should be imposed for land use purposes.^[15] Perhaps a change must be made to the customary form of reporting soil erosion loss, from mass of soil loss per hectare per year to an economic loss expressed in monetary values and associated with production and natural resource losses.^[11,15]

The effects of erosion on crop productivity are difficult to evaluate independently because of various interactions.^[8–12,15,16] Interactions occur among soil properties, crop characteristics, and climate, which should be accounted for when relating soil erosion and crop yields. Much of the soil's water and nutrient supply potential may be lost before the productivity loss is realized, because erosion effects are gradual, cumulative, not felt from year to year, and significant only over a long time period.

Furthermore, the combined effect on crop yield varies with the intrinsic characteristics of the soil and the specific soil management systems used. This is especially true because improved technology can offset the removal of plant nutrients and soil water storage capacity because of erosion and greatly mask erosion effects on crop yields, especially in the short term. Krauss and Allmaras^[16] stated that “sustained productivity of an eroding soil cannot be determined unless yield increases from technology advances are separated from soil productivity changes due to erosion.” Even with great obstacles, efforts to quantify

erosion's effects on crop productivity must continue. This information is fundamental in developing soil conservation plans and effective land use policies.

TECHNIQUES FOR EVALUATING EROSION IMPACT ON CROP PRODUCTIVITY

Several techniques have been proposed to evaluate the cause-and-effect relationship between crop yield and soil erosion.^[8,11] The direct method involves field experiments of short and long duration in which the soil of the test plot is naturally eroded by rain or artificially eroded by mechanical removal of the topsoil layer. With the direct method, productivity losses can be measured under field conditions, where crop performance, over a period of time, is related to soil loss or erosion-induced alterations in soil properties.

Overall, the direct method is more accurate than the indirect method but requires more capital, time, and labor to accomplish. The indirect method relates measured crop yields with estimated erosion losses from changes in physical and chemical soil properties occurring in the field. The crop productivity–soil erosion relationship is evaluated through mathematical, geomorphological, and crop productivity models. These models are less accurate than the direct method but require less time and labor and are cheaper to execute. Although satisfactory techniques are available to monitor soil erosion effects on crop productivity (i.e., the on-site damages), there is a lack of effective procedures to quantitatively evaluate sedimentation and water pollution impacts on the environment and human life (i.e., the off-site damages).

CONCLUSION

Soil erosion is a problem associated with human lives on earth. It threatens soil productivity, food production, the environment, and quality of life. Fortunately, erosion-induced problems have been well recognized, and sound control measures have been developed. To maintain the natural resources and environment for a sustainable civilization, soil erosion from agricultural lands must be controlled.

Erosion: Fly-Ash Spheres as Time Marker

Kenneth R. Olson

Department of Natural Resources and Environmental Sciences, University of Illinois at Urbana-Champaign, Urbana, Illinois, U.S.A.

Alexander N. Gennadiyev

Faculty of Geography, Moscow State University, Moscow, Russia

Abstract

Fly ash, the particulate matter resulting from high temperature combustion of coal, was historically dispersed into the atmosphere. Fly-ash spheres that settled on the surface soil were from a variety of boilers, including those of steam locomotives and steam-powered farm machinery. In the Central United States and western Russia, fly-ash spheres provide a time marker starting between the 1850s and 1910s and ending between the 1950s and 1960s. At many locations, fly-ash generation coincided with the development of railroads, cultivation, and settlements. These fly-ash spheres are stable and remain in the soils for more than a hundred years. Tillage and erosion can redistribute and reduce the depth of occurrence and the amount of fly ash present on upland cultivated side slopes. It appears that fly-ash spheres were initially deposited uniformly within the local landscape even when there were slight variations in aspect, elevation, slope gradient, and distance from the source. Erosion phases of soils on upland landscape positions can be determined based on the amount of fly ash remaining in soil surface layers. Accelerated erosion of cultivated side slopes results in deposition of fly-ash rich sediment on the adjacent foot or toe slopes. The proposed fly-ash method provides a tool to assess the extent of soil translocation from a cultivated upland landscape and subsequent deposition.

INTRODUCTION

In the Central United States and western Russia, fly-ash spheres provide a time marker starting between the 1850s and 1910s and ending between the 1950s and 1960s. Fly ash, the particulate matter resulting from high temperature combustion of coal, was historically dispersed into the atmosphere. Fly-ash spheres that settled on the surface soil were from a variety of boilers, including those of steam locomotives and steam-powered farm machinery. At many locations, fly-ash generation coincided with the development of railroads, cultivation, and settlement. These fly-ash spheres are stable and remain in the soils for more than a hundred years. Tillage and erosion can redistribute and reduce the depth of occurrence and the amount of fly ash present on upland cultivated side slopes. It appears that fly-ash spheres were initially deposited uniformly within the local landscape even when there were slight variations in aspect, elevation, slope gradient, and distance from the source. Erosion phases of soils on upland landscape positions can be determined based on the amount of fly ash remaining in soil surface layers. Accelerated erosion of cultivated side slopes results in deposition of fly-ash rich sediment on the adjacent foot or toe slopes. The proposed fly-ash method provides a tool

to assess the extent of soil translocation from a cultivated upland landscape and subsequent deposition.

TEXT

Fly Ash

Fly ash is a particulate matter resulting from high temperature combustion of coal. It is produced in a variety of boilers, including those in steam locomotives and steam-powered farm machinery (Fig. 1). The principal minerals in the coal of the Central United States and western Russia are feldspars, pyrite, siderite, quartz, calcite, and mostly kaolinite.^[1] The minerals are vitrified above 1473 K, and a common product is spherules composed of glass, quartz, mullite, wustite, and magnetite.^[2] Until technologies allowed removal of fly ash from stack gases emanating from boilers, the ash was a component of smoke and was deposited over a wide area around the sources, especially near coal-fired power plants. Further, sphere occurrence and abundance have been used to identify sediments laid down during the industrial epoch.^[3] The occurrence of ferromagnetic minerals, usually embedded in the glassy phase, offers a convenient

Fig. 1 Enlarged fly-ash sphere visible using a scanning electron microscope.

way to separate the spheres for identification and analysis. The use of fly ash and magnetic provides a time marker extending back between the 1850s and 1910s and is present in soils. The date coincides with Central United States and western Russia railroad development and initial period of American and Russian cultivation. Fly ash related to steam locomotive use was widespread by the 1920s in both countries. Some fly-ash spheres may have been derived from steam-powered farm equipment. Threshers and self-propelled tractors, the latter coming into greatest use from 1880 to about 1920,^[4] could have produced magnetic fly ash if their boilers were fed by soft (bituminous) coal. For economic and supply reasons, however, many steam boilers on farms were fired with straw or wood that probably could not produce highly siliceous, glass-phase fly-ash spheres.

Jones and Olson^[5] reported that fly-ash spheres were present in large amounts in soils and sediments near urban areas and in smaller quantities in rural locations within Illinois. Between the 1850s and present, every Illinois county had a railroad source of fly ash within or adjacent to the county. Fly ash had the potential of being an easily identified time marker in sedimentation studies. These airborne fly-ash spheres were first deposited on soils and sediments between the 1850s and 1910s, the time of settlement and the use of high-temperature coal-fired boilers, which are also nearly contemporaneous with initial American cultivation in Central United States. Fly-ash spheres were generated until the 1950s or 1960s when coal-fired locomotives were replaced. Fly ash present in soils can be used to identify sediments accumulated since Euro-American settlement and to interpret the stratigraphy of sediments and their relationships to the underlying soils.

The incidence of fly ash in soil profiles^[6–8] was aided by a study of carefully chosen sites near sources of the fly ash, e.g., undisturbed areas on Mississippi mounds at archaeological sites that were adjacent to and downwind from railroads. As some of the fly-ash particles should be in the silt- and sand-size range and not prone to eluviation, their distribution in the soil provides valuable information regarding biotic and abiotic mixing and pedoturbation of surface horizons since settlement. Knowledge of mixing characteristics helps interpret evidence of erosion or accretion in soil profiles as well as the time frame for these events.

Analytical Methods

The fly-ash sphere content was determined using procedures developed by Jones and Olson.^[5] A soil sample weighing 10 g was oxidized with sodium hypochlorite. Magnetic particles were separated by suspending this sample in distilled water and circulating it over a magnet wrapped in plastic film. The magnetic minerals were collected by removing the film from the magnet and washing the adherent particles into an evaporating dish. Extraction was repeated until no more particles were removed. This extracted sample was dried and weighted. The coefficient of variation for three duplicates was 6.6%.

The magnetic particle sample was then wetted with a minimum of water and mixed; a drop was transferred to a cover glass, dried, and carefully mounted with Canada balsam for petrographic microscope study (with strong oblique lighting). This type of mount facilitates scanning by presenting a flat field of magnetic particles on the cover glass bottom. The spheres were easily discerned

among the anhedral (or occasionally subhedral) opaque minerals, which were mostly magnetite, ilmenite, and leucoxene.

Fly ash was determined microscopically by choosing a random field using $\times 400$ – 1500 magnification (Fig. 2). A digital image of the field was made, and this image was analyzed for spherical particles using ImagePro image analysis software (Media Cybernetics, Silver Spring, Maryland, U.S.A.). Each spherical particle was identified by the microscopist and counted as fly ash. The metric reported an area of the fly ash as a percentage of the total area of opaque particles that were assumed to be ferrimagnetic. At least six fields were counted. The abundance of fly-ash spheres in the magnetic fraction was estimated, and each sample was placed in a category of <1.1 – 5% , 6 – 25% , 26 – 75% , or $>75\%$.

In order to compare sites and predict soil loss and gain from soil profiles, fly-ash sphere content needs to be determined and expressed on a volume basis. The fly-ash content (g m^{-2}) remaining on cultivated landscape positions can then be compared with the fly-ash content of the similar uncultivated landscape positions. The percent loss of the fly-ash content becomes an indicator of the percent reduction in the previous 20-cm soil surface layer of the cultivated and eroded landscape positions. The weight of the uneroded 20-cm thick surface layer on 1 ha can then be determined using measured bulk density and multiplied by the percent loss of the fly-ash content to determine the weight of the surface layer removed by erosion. Total weight of soil surface removed (Mg ha^{-1}) was divided by the number of cultivated landscape to determine erosion rate ($\text{Mg ha}^{-1} \text{yr}^{-1}$).

Cesium-137 activities were obtained by measuring the activity at 661.66 keV, using high-resolution spectrometric equipment, based on hyperpure germanium coaxial y-ray detector BDEG-30.195 with energy resolution 1.95 keV at energy line of 1332 keV and 30% efficiency. Count times were not less than 12 hours and were dictated by the appearance of well-shaped cesium-137 peaks.

Use of Fly Ash as Time Marker in Erosion Studies

In Southern Illinois, Hussain et al.^[9] observed higher amounts of fly ash in the A horizon for all landscape positions at an uncultivated site than at a paired cultivated site. These finding indicated the removal by cultivation and erosion of approximately 47% or 10.6 cm of the original surface layer in 142 years. Fly ash represented a better indicator of soil erosion than organic carbon (C), magnetic minerals, or magnetic susceptibility. Olson et al.^[8] used content of fly ash as an indicator of soil erosion at a site near Moscow, Russia. Replicated transects in cultivated and reforested sites were sampled and analyzed. The entire cultivated landscape contained 12% lower fly-ash content and magnetic susceptibility than the reforested site. These results suggested the loss of 2.4 cm of original A horizon and placed the soil in the slightly eroded phase.

The use of the fly-ash method made it possible to estimate the rates of erosion of plowed soils on southern and northern slopes. The uneven intensity of snow melting on southern and northern slopes induces uneven snowmelt runoff, so that the rate of erosion on the relatively warm south and west facing slopes was higher than that on the north facing slopes. Soil thawing on the slopes of southern

Fig. 2 Fly-ash field visible using a scanning electron microscope.

aspects is more active, and the duration of the period when the thawed soils are unprotected from erosion is larger on south facing slopes. On the basis of fly-ash method, the intensity of erosional processes on the slopes of different aspects at three key plots of Central Russia has been studied.^[10] The maximum steepness of the slopes at these plots was about 6°, 5°, and 3°, respectively. For leached and podzolized Chernozems (Argiudolls) of the Aleksandrovka plot, they reached 11 Mg ha⁻¹ yr⁻¹ on the southern slope and 2 Mg ha⁻¹ yr⁻¹ on the northern slope; for typical and leached Chernozems (Hapludolls) of the Gracheva Loshchina plot, 10 and 4 Mg ha⁻¹ yr⁻¹, respectively; and for typical and leached Chernozems (Hapludolls) of the Tolmachi plot (with the minimum slope), 6 and 4 Mg ha⁻¹ yr⁻¹, respectively. Thus, on all the investigated plots, soil erosion on the south facing slopes was more intense than that on the north facing slopes. In general, the difference between the rates of erosional processes on the slopes of northern and southern aspects for plowed soils was well pronounced on all the plots.

The fly-ash method was used for the quantification of the lateral migration of the solid-phase products of the pedogenesis within the catchment basins.^[11] This method allowed separating the spatial dispersion and accumulation zones of the soil material, which is genetically conjugated with one another and represents a component of the migration structure of the catchment basin. It was revealed that the manifestations of the dispersion and accumulation zones in the catchment area are of multifactor nature: the zones can be located on the upper, middle, and lower parts of the slopes; on the near watershed (near ridge) surfaces; and on the slopes of different exposures. The second component of the migration structure of the catchment basin included the formalized system of soil catenas within the territory. They can be classified with consideration for: 1) the transport rate of the soil material within the catenas; 2) the degree of their openness (i.e., the assessment of the portion of material removed beyond the catena limits); and 3) the localization of the zones of the soil material's accumulation on the slope.

Impact of Land Use, Erosion, and Landscape Position on Soil Organic Carbon (SOC) Stocks

Olson et al.^[12] found that the dynamics of SOC are affected by many factors including land use, management history, soil type, climate, and soil landscape processes. They compared the storage of SOC on sloping woodland and cropland landscapes of Northwestern Illinois. Soil erosion and sediment transport resulted in some SOC being redeposited in lower landscape positions but retained in the landscape. Results suggested that the cropland landscape retained 52% of the total SOC on a volumetric basis during cultivation, soil erosion, and agricultural use from 1860 to 2010. The other 48% of the SOC was either deposited in the water or released to the atmosphere.

Olson et al.^[13] determined the SOC level in a native timberland of west Central Illinois and then compared with the SOC levels in adjacent cropland and pastureland after agricultural use from 1860 to 2010. Results suggested that the cropland landscape retained 59.7 Mg C ha⁻¹ (87%) of the total SOC in the native timberland on a volumetric basis during cultivation and cropland use from 1860 to 2010. Soil erosion and sediment transport measured using the fly-ash method resulted in SOC being deposited in lower landscape positions but retained in landscape. The other 13% net loss of the SOC storage was either deposited in the water or released to atmosphere. The conversion of timberland to cropland increased soil erosion and reduced SOC storage, and any conversion to pastureland increased SOC storage and retention.

Use of Fly Ash and Cesium-137 as Time Markers in Transport Studies

Olson et al.^[14] used a radio-caesium (cesium-137) and a technogenic magnetic tracer (magnetic fly-ash spheroids) methods for the quantitative assessment of erosion, transport, and deposition processes. Both cultivated and uncultivated sites located near Springfield, Illinois, were compared. The fly-ash and cesium-137 methods did provide consistent results for six of eight cultivated and uncultivated landscape positions when significant deposition or erosion did not occur before the 1960s. The lower side slope site with a woodland/pastureland land use had significant erosion before the 1960s (reflected in fly-ash data) and eroded after cultivation in the 1960s. The relevant time period varied for both the fly-ash and cesium-137 methods. The fly-ash method assessed the soil stability, soil erosion, transport, and sediment deposition situation from 1860 to 2010, whereas the cesium-137 method assessed the soil stability, soil erosion, transport, and sediment deposition situation only from 1960 to 2010.

Olson et al.^[15] used both the fly-ash and cesium-137 methods to determine the amount and annual rate of soil erosion from 1960 to 2010 and from 1910 to 2010 time periods at a Knoxville, Illinois, site. Initially, the fly ash assessed the soil stability, soil erosion, and sediment deposition situation from 1910 to 2010 (based on time of coal-fired locomotives), whereas the cesium-137 method only assessed the soil stability, soil erosion, and sediment deposition situation from 1960 to 2010. After 1910, fly ash from coal-fired locomotives was deposited on the cropland. Using the 1910–2010 time period for the fly-ash annual erosion rate calculation and the 1960–2010 time period for cesium-137, the predicted annual erosion rates would be similar. However, the total amount of erosion was higher for the fly-ash method due to longer time period. The fly-ash and cesium-137 methods did provide consistent annual soil erosion rate results for five of five landscape positions on the cropland landscape positions even if the cesium-137 method uses the 1960–

2010 time period and the fly-ash time period was from 1910 to 2010. These combined method annual erosion rates ($0.7\text{--}4.0\text{ Mg ha}^{-1}\text{ yr}^{-1}$) for either from 1960 to 2010 or from 1910 to 2010 time periods are below the tolerable soil loss rates for the slightly eroded Rozetta and Hickory soils ($11\text{ Mg ha}^{-1}\text{ yr}^{-1}$).

The combined use of the fly-ash method and the radio-cesium method allowed assessing the spatial-temporal pattern of the sediment redistribution on typical slopes in different parts of the forest steppe zone of the East European Plain.^[16] A clear trend of the decreasing of soil loss rate in this zone from 1985 or 1990 to 2010 was revealed compared with the average rate 1860 or 1870 to 2010 period of plowing. The absolute values of the soil loss well agree with the data for the soil erosion rate in the forest steppe zone obtained using the conventional methods and approaches for assessing the intensity of the soil erosion. The obtained results confirmed the continuous nature of the soil erosion and accumulation during the transport of the sediments along the slope, which results in the alternation of the erosion zones and redeposition zones on the slopes.

Use of Fly Ash as a Time Marker in Depositional Studies

Kreznor et al.^[17,18] quantified the postsettlement deposition in a 2.49-ha sediment basin with a single outlet in a 10.54-ha watershed and estimated the sediment delivery to a first-order stream in Northwestern Illinois. Buried A horizons (dated using fly ash as a time marker) identify the presettlement (1854) surface, which was overlain by as much as 116 cm of sediment. Volume of the sediment within the basin was calculated at 34 m^3 with a mass of 16,480 Mg. The modern soils of the sediment basin were characterized and classified, and the spatial variability of the sedimentation process was examined. Based on representative measurements of postsettlement sediment delivery obtained from research of drainage basins having similar size or soil characteristics, it was inferred that 20,975 Mg of sediment was delivered to the stream and with a total of 37,455 Mg of sediment being removed from the watershed hillslopes as a result of accelerated soil erosion. The measured rate of post settlement sediment accumulation was approximately 0.34 cm yr^{-1} .

Olson et al.^[19] studied a nearly level plot area near Monmouth, Illinois, with Muscatune and Sable soils. The fly-ash method was used to determine the extent of erosion as a result of cultivation between 1880 or 1910 to 2010. The fly-ash rich sediment being transported to and deposited on the adjacent Sable soil in the sample plot area was measured. For the 0–50 cm layer, the Sable soil fly-ash content is 19% higher than the Muscatune soils. The erosion rate, using the fly-ash method, was $4.35\text{ Mg ha}^{-1}\text{ yr}^{-1}$. Approximately, 6 cm of the total difference of 21 cm between Sable and Muscatune A horizons thicknesses was

a result of erosion of the Muscatune soil and deposition on the Sable soils.

CONCLUSION

Fly-ash sphere method can be used as a time marker in erosion, transport, and depositional studies. The soil erosion rates and depositional rates can be measured for from 1910 to 2010 or 1860 to 2010. Erosion phases of soils can be determined on upland landscape positions based on amount of fly ash remaining in soil surface layers. The fly-ash method has been used to determine the effects of aspect on soil erosion rates and to quantify lateral migration of solid-phase products within catchment basins. The sediment depositional rate can be measured using the presence or absence of fly-ash spheres in buried soil layers. The effect of land use change, erosion, transport, and deposition on SOC stock can be determined by landscape position and weighted for the whole landscape in each land use.

Yin Liang

Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China

Abstract

China is one of the nations that is most severely affected by soil erosion in the world. The land area affected by accelerated soil erosion was estimated to be 295 Mha in 2010, and the average annual soil loss due to soil erosion is estimated to be 5000 million tons. On a global scale, the total land area affected by soil erosion is 1643 Mha, and the annual soil loss due to accelerated soil erosion is estimated to be 75 billion tons. As the most serious and widespread form of soil degradation and an important form of global change, soil erosion severely threatens the quality of soil, air, and water resources and hence menaces agricultural development, ecological civilization, and human well-being. Soil erosion and global climate change are related by bidirectional interaction, and soil erosion is likely to significantly increase under global climate change unless effective amelioration measures are taken in time. Therefore, it is critical to take scientific and effective actions against soil erosion.

INTRODUCTION

Soil erosion is the movement and transport of soil by various agents, particularly by water and wind, which lead to a loss of soil. Usually, soil erosion takes place very slowly in natural ecosystems, but it can occur at accelerated rates in areas where landscapes are disturbed improperly by human activities. Global change has increasingly become a great concern since it was put forward by the International Council for Science in 1986. Global change, as a result of physical, chemical, and biological processes in the earth's system—particularly of interactions between humans and the environment—refers to the changes in global environmental components that are vital to human survival, such as climate, land, water, and air, in the forms of greenhouse effect/global warming, diminution of forest, loss of biodiversity, degradation of land, and deficiency in water resources. These global changes represent the major global challenges the humankind are facing. Soil erosion is an important form of global change and severely threatens the quality of soil, air, and water resources, hence undermining agricultural development, ecological civilization, and human well-being. Soil erosion and other forms of global changes are related by bidirectional interactions, and notably, global climate change may exacerbate soil erosion. Although it is a daunting task, soil conservation has been greatly advanced through effective soil and water conservation measures in China and other regions of the world.

THE CONTRIBUTION OF SOIL EROSION TO MAJOR GLOBAL CHANGES/CHALLENGES

Extent of Soil Erosion in China and in the World

China is one of the nations that is most severely affected by soil erosion in the world. The land area affected by accelerated soil erosion was estimated to be 295 Mha in 2010, including 129 Mha by water erosion and 166 Mha by wind erosion (Table 1).^[1] The average annual soil loss due to soil erosion is estimated at 5000 million tons, including 2350 million tons from the watershed of Yangtze River and 1581 million tons from the watershed of Yellow River.^[2] The region most severely affected by soil erosion in China is the watershed of Yellow River (Fig. 1), with an erosion area of 40.2 Mha and an erosion modulus of $4840 \text{ t km}^{-2} \text{ yr}^{-1}$, especially in the Loess Plateau with an erosion modulus as high as $30,000 \text{ t km}^{-2} \text{ yr}^{-1}$ and an annual soil loss of 1.63 billion tons.^[2] Fortunately, about 24% of erosion area in the Loess Plateau has been controlled since the 1980s.^[3]

On a global scale, total land area affected by water erosion is 1094 Mha, of which 751 Mha is severely affected, and that by wind erosion is 549 Mha, of which 296 Mha is severely affected (Table 2).^[4–6] Worldwide, the annual soil loss due to accelerated soil erosion is estimated at 75 billion tons.^[7] Most of the eroded area is distributed in Africa and Asia, accounting for 64.7% of water erosion area and 63.5% of wind erosion area in the world (Table 2).

Table 1 Area affected by accelerated soil erosion in China.

Erosion grade	Water erosion (Mha)	Wind erosion (Mha)
Slight	66.76	71.60
Moderate	35.14	21.74
Severe	16.87	21.82
Very severe	7.63	22.04
Extremely severe	2.92	28.39

Soil Erosion Threatens Global Food Security through Degrading Soil Quality

Soil is one of the most important natural resources and a major factor in global food production. Soil erosion is widely considered as the most serious form of soil degradation.^[8] When soil erosion rate exceeds soil development rate, it would lead to soil degradation and pose a significant threat to world's food production capacity and global food security. Approximately, one-third of the world's agricultural land has been affected by soil degradation in the past years, and most of this damage is attributed to water and wind erosion. It is reported that the soil erosion rate is 1–2 magnitude orders greater than the soil development rate on conventional plow-based agricultural lands.^[9] The average rate of soil loss in agricultural areas has been estimated at $17 \text{ t ha}^{-1} \text{ yr}^{-1}$ in the United States and Europe and $30\text{--}40 \text{ t ha}^{-1} \text{ yr}^{-1}$ in Asia, Africa, and the Southern United States, mainly due to inappropriate land use and management.^[7] It is estimated that the annual global topsoil loss from agricultural lands due to water erosion is 20–30 billion tons.^[10]

Soil erosion reduces area of arable land and leads to depletion of nutrients. Increases in the vulnerability of soils

Table 2 Area affected by accelerated soil erosion in the world.

Region	Area affected by severe erosion (moderate + level; Mha)	
	Water erosion	Wind erosion
Africa	169	98
Asia	317	90
Europe	93	39
Central America	45	5
North America	46	32
Oceania	4	16
South America	77	16
World	751	296

to erosion suggest that more organic matter and mineral nutrients will be lost from soils, leading to a decline in ecosystem-sustaining characteristics such as water-holding capacity, plant productivity, and biodiversity.^[9] The process has exerted a profound effect on the balance of world food supply, although the on-site effects of soil erosion on crop productivity are easily minimized through additional external agricultural inputs and improved agricultural technologies. Soil erosion and its effects on crop production have been extensively investigated since the turn of the 20th century. The tolerable erosion rates have been quantified to describe the maximum rate of soil erosion that can permit crop productivity to be sustained economically and maintained indefinitely. The negative effect of erosion on crop productivity can be assessed using field runoff plots or paired watersheds. The actual loss may depend on weather conditions during growing season, farming systems, soil management, and soil ameliorative inputs. Simulation models have been developed to predict the effects of erosion on soil properties and crop

**Fig. 1** Landscape of severe soil erosion in the Loess Plateau of China.

responses.^[6] By linking with geographic information system tools, these models can be expanded to the regional, national, and global scales, and the dynamics of agricultural management can be studied.^[11,12] According to the loss rate, 9933 km² of surface black soil (mollic epipedon) on agriculture land will be lost, and crop yield will decrease by 40% in the northeast China in 50 years if no effective countermeasures are implemented.^[13] Loss estimates of partial global food suggest that annually farmers lose about 2.2 million tons of maize, 0.07 million tons of millet, 1.1 million tons of potatoes, 0.1 million tons of soybeans, and 1.1 million tons of wheat, which may be more severe in Asia, sub-Saharan Africa, and other tropics.^[8] Furthermore, as a driver of land use change, soil erosion will induce abandonment of arable land due to declining productivity^[14] and exacerbate poverty and hunger since the poverty and soil erosion are related by bidirectional interaction; generally, the poorer areas are also the areas affected by severe soil erosion.^[13]

Soil Erosion Deteriorates Global Environment and Ecological Civilization

Soil erosion deteriorates the global environment through flood disasters, environmental pollution, desertification, etc. It aggravates flood disasters through raising riverbeds, silting lakes, and shrinking water bodies. On a global scale, about 0.5–1.0% of water storage is lost annually as a result of sedimentation.^[15] The economic cost of reservoir storage losses is reported more than \$13 billion, excluding other environmental and social costs incurred from additional dam development.^[16] In China, flood disasters increased from once per 20 years 1300 years ago to once per 1.6 years in the 1990s in the Yangtze River Basin due to soil erosion. Riverbed in lower reaches of Yellow River was raised by 8–10 cm per year due to soil erosion.^[1]

Soil erosion is also an important non-point source of pollution. With enrichment of nutrients, heavy metals, and pesticides in sediments and a large amount of rapidly available nutrients in surface runoff, water erosion can cause serious damage to the water quality and aquatic ecosystems in receiving waters. In contrast, wind erosion can have an adverse effect on transportation, communication, and human health through increasing dust in the air, being most adverse in the case of dust storm, which is the most intensive and powerful form or consequence of wind erosion and recognized as a disastrous weather. The most well-known dust storm are those that swept over the southern areas of the United States in the 1930s and that have afflicted Northern China including Beijing, the capital of China. The off-site damage from wind erosion in the United States is estimated to be nearly \$10 billion each year.^[7] It is reported that about 20 human infectious disease microorganisms, such as anthrax and tuberculosis, be present in the soil particles transported by wind.^[17] In addition, soil erosion by water or wind can be a driving force to soil desertification; e.g. the area of rocky desertification

resulted from soil loss due to water erosion is estimated to be doubled in the karst region of southwest China in 35 years, if no scientific and effective actions are taken against the soil erosion in the region.^[13]

Soil erosion influences global climate change by changing the cycles of carbon, nitrogen, and water. The global soil carbon pool is about 2500 Pg, 3.3 times the size of the atmospheric pool and 4.5 times the size of the biotic pool.^[18]

Small changes in the pools of carbon and nitrogen in soils could have large effects on atmospheric concentrations of carbon dioxide (CO₂), methane, and nitrous oxide. Soil erosion has a profound impact on the quality and quantity of soil organic matter (SOM) and can be a significant factor in losses and redistribution of local carbon reservoirs. It is estimated that 0.8–1.2 Pg C emission is added to the atmosphere annually due to global soil erosion,^[6] which contributes to the global warming problem. The effect of water erosion would become more important in the global carbon budget, because it will be strongly influenced by climatic change and land use in many regions.^[19] However, it is uncertain whether the increased sediment yield results in a net carbon sink into passive carbon pools or a net source into the atmosphere as a result of mineralization of labile carbon.^[6]

Soil erosion may cause a shortage of freshwater through deteriorating soil physical structure, increasing surface runoff while less water entering the soil, and changing global water cycling. Compared with uneroded soils, moderately eroded soils retain 10–300 mm less water per hectare per year from rainfalls. This represents a decrease of 7–44% in available water for plant growth and most likely results in water shortage for crops in farmlands.^[20] In China, the annual average of drought-affected areas has reached 22.3 Mha during the period of 2000–2012, most of which are located in the areas severely eroded.^[1,21]

As mentioned above, soil erosion leads to a decrease in overall biomass and productivity by degrading soil quality. Ultimately, this has a profound effect on the diversity of plants, animals, and microbes in the entire ecosystems based on eroded soils. In areas where erosion rates are 10–20 times higher than soil formation rates, the diversity and abundance of soil organisms are significantly decreased. On the contrary, when biomass is increased due to soil conservation remedies, the number of species can be increased appreciably. It is reported that a 10-fold increase in bird diversity was seen with a 100-fold increase in plant biomass production.^[20] In addition, soil erosion has indirect effects on ecosystems as damaging the effects of decreasing plant biomass productivity. For example, a grassland with reduced plant richness due to soil erosion is more susceptible to drought than the one with an abundance of plant species.^[22] Sometimes, soil erosion may cause the loss of a keystone species and then lead to cascading effects on the survival of a wide range of other species within the ecosystem.

Through degrading soil quality, soil erosion may cause changes to landscapes and ecosystems on local, regional, and global scales, altering the delivery of ecosystem

services, microclimates, and even the global climatic pattern and ultimately jeopardizing the construction of ecological civilization.

Global Climate Change May Accelerate Soil Erosion

The main factors controlling soil erosion are the erosivity of eroding agents (rainfall and wind), the erodibility of soil, the slope of land (slope steepness and length), and the nature of plant covers. Erosion processes and their influential factors vary according to the studied scale. Therefore, soil erosion forecasting is associated with time and space scale, from the field scale at which it affects the individual farmer, up to national or global scales where it can make an important contribution to decision or policy makers. Since the 1950s, significant advances have been made in predicting erosion risks under different conditions, particularly with the development of modeling technology.^[23] However, the response of soil erosion to global climate change is complex temporally and spatially due to uncertainties in general circulation models and the complex relationships of soil erosion processes with climate, land use, and land cover.

Changes in greenhouse gases concentration and climate will change the hydrologic cycle and hence affect the soil–plant–water interactions, which in turn affect soil erosion. Detachment and transport of soil by water depend on the amount and intensity of rainfall, which is directly affected by changes in climate. Results from modeling show that rainfall erosivity is projected to increase significantly with the projected climate change.^[12] The responses obtained by models such as LISEM, MEFIDIS, RUSLE, STREAM, KINEROS, SWAT, and WEEP to rainfall change indicate that soil erosion is likely to increase significantly under climate change unless amelioration measures are taken.^[24] Average annual runoff rates are expected to increase by 30% to 40% in high latitudes and decrease by 10% to 30% in arid and semiarid regions prone to drought stress.^[25] Increases in air temperature may lead to faster rates of snow melting, which can result in higher snowmelt runoff. The predicted climate change is expected to increase the risks of soil erosion, and the magnitude of this expected increase in water and wind erosion risks will most likely depend on local and regional conditions.^[26,27] In some regions, any increase in rainfall (e.g., amount, intensity, and frequency) as a result of climate change may directly exacerbate erosion. On the contrary, in other regions, a decrease in rainfall may be expected. In this case, a decline in soil moisture because of the enhanced evaporation will occur. Drier soil conditions and less vegetation can make soils more vulnerable to wind erosion. Moreover, soil erosion tends to be dominated by extreme events. An increase in the possibility of extreme rainfall events, which is suggested by several climatic change models, may accelerate soil erosion.

Global climate change may influence soil erosion through changing temporal and spatial evolution of global

soil cover, such as changes in soil-forming processes and soil properties associated with soil erodibility. The response of soil to the erosion process is complex and closely related to soil properties such as texture, structural stability, organic matter content, clay mineralogy, and chemical constituents. All these factors are likely to change with climate and/or land use. The increasing air temperature may accelerate the SOM decomposition rate, severely deplete the SOM reserves, and increase soil erodibility.^[28] A decline in SOM level would cause a decrease in soil aggregate stability, lower infiltration rates, increase in runoff, and then increase in the likelihood of soil erosion. The increased atmospheric CO₂ concentrations will enhance plant growth. However, the beneficial effects of high CO₂ concentrations on biomass production may be offset by increasing air temperature and reduced precipitation in dry regions.^[12] The change in the magnitude of soil erosion risk with the reduction in SOM is a clear manifestation of the impact of global warming on soil erosion risk. Fortunately, the impacts of SOM on climate change and food security have been concerned, and some strategies such as less till and no-till farming systems to increase SOM have been proposed.^[18]

Major changes in wind erosion rate driven by climate change would be associated with local or regional changes in soil moisture and vegetation. It is reported that wind erosion will increase on grazing lands of the Southwestern United States because of increased aridity and associated reductions of vegetation cover.^[29] Increased wind erosion is also likely to increase the incidence of wildfires, which in turn will increase wind erosion rates as well as water erosion rates due to the drastic reductions in ground cover after wildfires.^[30] Model projections predict the trends of decreasing wind speed in some regions, likely leading to a decrease in evapotranspiration in cropping regions and the potential for wind erosion.^[31]

Sea level change is also an important item in global change as a result of global warming. A research indicates that more coastal erosion is triggered by sea level rise,^[32] e.g., annual beach sediments loss was $1.67 \times 10^4 \text{ m}^3$ due to sea level rising in the southern Shandong sandy coast in China.^[33]

Soil and Water Conservation in China under Global Climate Change

The severe consequences and grim projections of soil erosion' impact on global food security and environmental and ecological sustainability as described earlier emphasize the need to implement soil conservation strategies and practices. The basic principle underlying all these strategies and practices is to keep the land protected from wind and water energy by constructing some form of vegetative cover on the land. An array of soil conservation techniques has been developed for various erosion types under different natural and economic conditions. In China, the national strategies for soil erosion control are as follows: 1) prioritizing

Fig. 2 Severe soil erosion in the sparse Masson pine forest in subtropical China.

prevention and conservation measures; 2) promoting integrated small watershed management with focus on sloping croplands and gully-eroded areas; 3) ensuring closed/forbidden areas from disturbance for ecological recovery on their own; 4) planning goals and measures specific for individual target zones according to local conditions; and 5) strengthening leadership by establishing comprehensive management mechanisms. Since 1978, China has launched some of the world's most large-scale conservation programs, including the Three Norths Shelter Forest Project, Grain for Green Project, and the Natural Forest Conservation Program, which together cover almost entire mainland China except five eastern coastal provinces.^[34] About 30 years after these programs were implemented, the environment and society in project areas have been improved greatly as indicated by more acreage of green lands and less population in poverty, avoiding the vicious cycle in which poverty leads to environmental damage, which in turn deepens poverty.^[34] According to the meteorological observation in Beijing, the capital of China, dusty weather event including dust storm has shown a trend of decrease in frequency and intensity since 2000, which is coincided with the progress in vegetation restoration associated with these ecological programs within Beijing and its neighboring areas. However, strong dust storm still outbreaks now and then in northern areas of China including Beijing. Nearly 290,000 km² of sandy lands in the northern areas of China remain to be greened up, some of which is the dust source of dust storm outbreaks in Beijing.

The land area affected by soil erosion decreased by 4900 km² annually in the humid South China due to afforestation and soil and water conservation activities. However, unreasonable vegetation construction cannot effectively control soil erosion; e.g., severe soil erosion was observed in the sparse Masson pine forest in subtropical China (Fig. 2).^[35]

In agricultural areas, where soil erosion is usually a severe problem, if production systems are integrated with appropriate conservation management systems, the adverse effects of climate changes such as increased precipitation amounts and intensities on soil erosion can be alleviated. The major conservation practices or technologies include the use of crop rotation, less till and no-till, biomass mulches, cover crop, contour cropping, shelterbelts, grass strips, and various combinations of these techniques. The adoption of these techniques can also improve soil quality by increasing SOM content and forming good soil structure, both of which may improve the water-holding capacity of soils and hence could strengthen the adaptability of water management during drought.^[36]

CONCLUSION

Soil erosion is an important form of global change; severely threatens the qualities of soil, air, and water resources; and

hence menaces agricultural development, environmental quality, ecological civilization, and ultimately human well-being. Soil erosion and global climate change are related by bidirectional interaction, and soil erosion is likely to increase significantly under global climate change unless amelioration measures are taken. Therefore, it is critical to take scientific and effective actions against soil erosion. The potential for global climate change to increase the risk of soil erosion is undoubtful, but the actual damage is not clear. More work should be done to refine the modeling of soil erosion under the scenarios of global climate changes in different regions. During the combating of its serious soil erosion problem, China has accumulated a wealth of knowledge and experience in soil and water conservation practices, which could be useful for other countries and regions that face the soil erosion issue alike.

Erosion: On-Site and Off-Site Impacts

Jerry L. Hatfield

National Laboratory for Agriculture and the Environment, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Ames, Iowa, U.S.A.

Abstract

Erosion, either by wind or by water, moves large amounts of soil each year. Erosion is the process of moving soil by the action of water or wind from one location to another in the landscape and often over large distances as off-site impacts. Redistribution of soil within the field is often overlooked as a major impact of erosion processes compared to the more visible off-site movement that is often seen as alluvial fans in streams and rivers or the dunes of sand in highly erodible arid regions. Continued loss of topsoil removes the most productive portion from the soil profile, and although nutrients and water can be resupplied to the soil, the productivity levels remain affected. The major on-site impact of erosion is the loss of crop productivity, and this is mirrored in reductions in crop yield and water use efficiency and nutrient use efficiency. In regions of the world with variable rainfall, the loss of topsoil increases the vulnerability of human food supplies.

INTRODUCTION

Erosion, either by wind or by water, moves large amounts of soil each year. It has been estimated that over 80% of the world's agricultural lands are affected to some degree by erosion.^[1,2] Continued loss of topsoil removes the most productive portion from the soil profile, and although nutrients and water can be resupplied to the soil, the productivity levels remain affected. The major on-site impact of erosion is the loss of crop productivity, and this is mirrored in reductions in crop yield and water use efficiency and nutrient use efficiency. In regions of the world with variable rainfall, the loss of topsoil increases the vulnerability of human food supplies. Off-site impacts of erosion relate to the economic and ecological costs of sediment, nutrients, or agricultural chemicals being deposited in streams, rivers, and lakes. Adoption of soil management practices to reduce erosion can have profound effects on future world food supplies.

Erosion is the process of moving soil by the action of water or wind from one location to another in the landscape and often over large distances as off-site impacts. Redistribution of soil within the field is often overlooked as a major impact of erosion processes compared to the more visible off-site movement that is often seen as alluvial fans in streams and rivers or the dunes of sand in highly erodible arid regions. Erosion processes are responsible for the shaping of the canyons, creation of the Palouse areas in Washington, and the loess deposits in both China and the United States. Erosion is a powerful force at work in the agricultural lands of the world. It has been estimated that almost 56% of the world's agricultural lands have been degraded by water erosion, while 28% have been degraded by wind erosion. Continued degradation of world agricultural lands by erosion threatens the stability of food production.^[1–3]

ON-SITE IMPACTS

Topsoil in agricultural fields has been removed since humans began farming. Evidence of this effect is seen by the level of agricultural fields compared to adjacent fence rows or native pastures. Removal of this topsoil has a large impact on the ability of the soil to produce food, feed, or fiber. On-site impacts of erosion are evident in the productivity levels of the soil. Erosion removes the topsoil that is highest in organic matter content, has the most stable soil structure, and offers the most optimal seedbed for germinating and emerging plants. The upper layers of soil are those that reflect the influence of anthropogenic activities. Removal of the topsoil reduces the water-holding capacity of the soil and further reduces the available rooting depth of the crop. All of these changes have a negative impact on soil productivity. Soil productivity levels represent the potential capability of the soil to produce a crop under optimal meteorological conditions. Therefore, any removal of soil would reduce this potential (Fig. 1).

There is a large variation among soils in their response to erosion. Temperate soils are less affected by erosion than tropical soils; however, in both soils, productivity is negatively affected. In tropical soils, the on-site impacts vary among crops. Cereal crops are more affected than root crops.^[3] Similar responses are seen for other areas of the world. Continued erosion will cause a shift in the types of plants that can be grown on a given soil. Erosion effects can be modified by the use of inputs (nutrients, tillage, and supplemental supplies of water). However, adding soil nutrients is not often a replacement for the natural productivity of the soil. Rooting depth of the crop is restricted more in eroded than in non-eroded soils. Problems with

Fig. 1 Erosion dissects productive cropland with water flow and sediment movement through fields.

rooting depth and extensive root development reduce the efficiency of water and nutrient use by the crop.^[4–6]

On-site impacts of soil erosion are difficult to quantify. Crop production levels (yields) are often the most common measure of soil performance. However, the measurement of water use efficiency or nutrient use efficiency provides a more quantitative method of being able to compare among locations or crop species. Water use efficiency and nutrient use efficiency (expressed as the amount of grain or total biomass produced relative to the amount of water used and nutrient applied, respectively) provide a measure of the capability of the soil to produce a crop. In wheat, removal of the upper 0.18 m of the soil profile reduced the water use efficiency by 20%, but did not affect the amount of water used by the crop.^[7,8] Nutrient use efficiency in the wheat was affected, and it was found that additions of either nitrogen or phosphorus fertilizers to eroded soils did not restore productivity to the non-eroded levels.^[4] In tropical soils, erosion reduced the water use efficiency by 60% with 0.35 m of erosion and reduced nutrient use efficiency of the non-eroded soil by over 500%.^[2] These examples are typical of the responses that have often been observed when crop production efficiency has been studied. Efficiency of crop production diminishes with decreasing topsoil depth.

In Africa—where much of the crop production is by subsistence agriculture—the loss of 0.4 m of topsoil could reduce crop yields by over 75%.^[3] A conceptual diagram of the potential changes in productivity and required production inputs is shown in Fig. 2. This level of reduction would increase the potential vulnerability of food supplies to weather variation within the growing season or climate changes across years. Erosion would have a larger impact on productivity in arid and semiarid environments—where water is a limiting component in crop or forage production—than in the temperate or tropical climates.

Fig. 2 Conceptual diagram of the effect of topsoil removal on the input and output changes in agricultural systems.

In addition to the removal of the topsoil from the field, an on-site impact is often the disruption of cultural operations because of gullies or rills in the field. The generation of eroded areas within the field can cause problems with all cultural operations that result in damage to machinery or increased labor costs to repair these problems.^[2] Deposition of soil within a field can create problems by burying emerging crops, and often the moving water transports crop residues from previous crops to low-lying areas of the field. Another on-site impact that occurs is the deposition of soil that contains agricultural chemicals onto adjacent fields. These chemicals can cause problems with crop growth, particularly if the crop in the adjacent field is sensitive to the particular chemical. This effect is seen in localized sites, but the impact is often large if there are high-value crops being grown (Fig. 3).

Fig. 3 Surface runoff occurs in fields and removes large amounts of soil and crop material.

OFF-SITE IMPACTS

Off-site impacts are those linked with the transport and deposition of soil from production fields or paddocks onto adjacent or downstream areas. These impacts can be classified into two major components: economic and environmental. Economic impacts of either water or wind erosion are difficult to quantify. Costs associated with the removal of eroded soil from roads after floods or windstorms are billions of dollars each year.^[1] This amount does not include the amount of money spent on repairing damage caused by sediment deposited in homes after floods or the costs associated with temporary housing. These off-site impacts are often the ones that are most noticeable due to water and wind erosion. Other economic impacts of erosion are the removal of sediment from lakes and rivers to maintain navigation, recreation, or flow.

Environmental impacts from erosion may take a longer time to be noticeable. Sediment deposition into streams, rivers, and lakes impacts the biological health of the ecosystem. The presence of excessive sediment in the water column disrupts the ecological balance, and it is difficult to place a monetary value on this impact. Sediment that is moved off-site may contain nutrients, in particular phosphorus, agricultural chemicals, or pathogens. Each of these components has an impact on the ecosystem. Excess phosphorus can cause eutrophication in water bodies that leads to diminished productive capability and water quality problems.^[9] Phosphorus movement is mainly through attachment to sediment, and movement of soil from fields often transports large amounts of sediment-bound materials.^[10] Likewise, many agricultural chemicals are tightly bound to sediments and only move off-site when soil is transported. Transport of agricultural chemicals (herbicides or insecticides) poses health hazards to both fish and humans if the concentration in the water supply exceeds toxic levels. Treatment of drinking water supplies to remove agricultural chemicals varies across regions; however, annual costs that exceed \$500,000 in water treatment facilities have been reported (L.D. McMullen, Des Moines Water Works, Personnel Communication, 2000). Environmental quality aspects of erosion are more evident in the effect of materials bound to the moving sediment than sediment itself.

Transport of pathogens from agricultural lands to adjacent waterbodies has become one of the most important topics in agricultural watersheds. Pathogens may impact fish and human populations, and the tragedy in Milwaukee, Wisconsin, with the deaths of over 20 people from waterborne pathogens, shows the potential of off-site movement to affect human life. Movement of sediment and nutrients has been considered to be the largest off-site impact and the most costly.^[9,10] However, transport of pathogenic material from fields or stream banks into water supplies is emerging as one of the critical problems in watershed management, and scientific papers to evaluate the cause and effect relationships will emerge from these observations.

Off-site impacts from wind erosion are often characterized as nuisances because of the problems with deposition of windblown materials. The cost of removing these deposits is less compared to the costs of removing sediment. There is also a nuisance factor caused by reduced visibility; however, there are direct human health concerns associated with increased particulate loads and soilborne pathogens in the air.

CONCLUSION

Erosion has a major impact on both on-site productivity and efficiency of production. It is difficult to develop an exact cost figure for erosion. However, continual degradation of the soil through erosion threatens the stability of future food supplies. Off-site impacts of erosion affect both water and air quality. Increasing concern about the potential impacts of off-site movement of nutrients, chemicals, and pathogens on water quality will continue to be a major concern in how we view the soil resource and implement practices to protect soil. Decreasing erosion will have positive on-site and off-site impacts.

Erosion: Overland Research and Measurement Techniques

Chia Chun Joseph Wu

National Pingtung University of Science and Technology, Neipu, Taiwan

Abstract

Water erosion initiates from uplands and continues its action through transportation and deposition. It normally produces 0.03 ~ 64 t/ha of soil loss annually. However, it can greatly accelerate to 3 ~ 750 t/ha of sediment annually when cultivation is involved. Measurement techniques are required to understand as well as quantify the erosion processes. Progress in technology has advanced the measurement instrumentation from manual to automatic oriented. Nevertheless, researchers need to identify their studies' objective, the environment in which their studies being conducted, and the characteristics of sediment before making selection of the suitable measurement techniques. Water erosion measurement techniques associated with overland erosion processes are addressed in the entry. Examples of Universal Soil Loss Equation standard runoff plots and small plots are illustrated through figures. Volumetric sediment collection and micro-topography measurement devices are also addressed. Cautions addressed in the entry may require additional attention while selecting water erosion measurement techniques.

INTRODUCTION

In the early days, erosion controls were mostly implemented on a trial-and-error basis with little assurance of the outcome. Loss of lives and properties as well as overdesign of counter-measures had finally caught researchers' attention to quantify the soil loss caused by water erosion. The first effort to quantify water erosion processes was initiated in 1914. The Dust Bowl in the early 1930s attracted public attention in soil erosion. A joint federal-state committee was appointed, and soil erosion experiment stations were established at different geographic locations representing a wide range of soils and climatic regions throughout the United States.

Built upon over 10,000 plot-years of data, a soil loss estimation tool, known as Universal Soil Loss Equation (USLE)—involving the multiplication of six key important factors—was introduced to both academic and field application arenas. These key factors include rainfall erosivity, soil erodibility, slope length, slope steepness, cover and management, and support practice factors.

Soil loss estimation techniques have gone through a gradual transformation since the 1970s from solely empirical-based models to process-based models. Despite the complexity of process-based models, USLE serves as an important guideline for the advances in water erosion research, and water erosion measurement techniques developed throughout the chronicle of water erosion research are commonly employed in the research community.

WATER EROSION MEASUREMENT TECHNIQUES

Soil loss and non-point source pollution estimation has gained greater interest in the last decades for the

purposes of conservation planning and policy making, which has shifted federal funding from fundamental researches to modeling. For instance, ANSWERS (Areal Nonpoint Source Watershed Environment Response Simulation),^[1] CREAMS (Chemicals, Runoff and Erosion from Agricultural Management Systems),^[2] EUROSEM (European Soil Erosion Model),^[3] and WEPP (Water Erosion Prediction Project)^[4] have extended soil loss estimation from hillslope to watershed. Nevertheless, every mathematic module embedded in a simulation model requires scientific sound support obtained from fundamental researches. Hence, field as well as laboratory erosion research requires appropriate measurement techniques and adequate experiment design. Therefore, the following sections address the common measurement techniques in water erosion.

Rainfall Erosivity

Rainfall erosivity factor describes the potential of rainstorm in water erosion. It is formulated as the product of rainfall kinetic energy (E) and maximum 30-minute rainfall intensity (I_{30}).^[5,6] The maximum 30-minute rainfall intensity can be easily extracted from rainfall records. However, rainfall kinetic energy is less straightforward. Drop size distribution representing the local climatic condition must be measured prior to the development of rainfall erosivity factor.

Several techniques have been developed for drop size measurement. They include the flour pellet method,^[7] stain method,^[8] oil method, high-speed photography, laser method, and momentum method. The high-speed photography, laser method, and momentum method require sophisticated equipment to collect raindrop data, and the instrumentation can be costly. The flour pellet method

requires a longer time for preparation prior to implementation. It also requires consideration of the raindrop-induced pellets postprocess. It is greatly affected by the humidity of the working environment, which may cause variability in the drop size measurement. The oil method, on the other hand, is less difficult to prepare but more difficult to transport for outdoor measurement. The stain method, with the assistance of an image scanner,^[9] is probably the most cost-efficient and labor-efficient technique for raindrop size measurement.

By combining the drop size distribution, rainfall intensity, and terminal velocity, the rainfall kinetic energy can be determined. Due to geographic variability in rainfall characteristics, rainfall erosivity factor is the most needed parameter that requires local attention. It also requires long-term measurements to obtain a representative index with a wide spectrum of intensities for local climate.^[10]

Soil Erodibility

Soil erodibility describes the potential of a soil in resisting soil erosion. The higher the erodibility a soil possesses, the less resistant the soil is to erosion. Soil erodibility can be determined from the soil loss measurement on a USLE standard runoff plot if it is accessible. Otherwise, it can be determined by measuring aggregate stability, soil properties related to water transmission or to water retention.^[11]

USLE Standard Runoff Plot

USLE standard runoff plot has a slope length of 22.1 m with various plot widths designed to meet the research objective. It is installed on a 9% uniform slope. The plot has to be in fallow condition with up-and-down plowing for two consecutive years. Use of USLE standard plot is highly recommended for those regions with a limited soil erodibility data.

Soil erodibility can be determined by dividing annual soil loss by annual rainfall erosivity. Reliable soil erodibility data may require a monitoring period much longer than 2 years, especially when cropping factors are considered. Using rainfall simulators on small plots provides an alternative for soil erodibility measurement.

Small Plot

Moldenhauer^[12] once used a rainfall simulator on small plots to study the effects of soil characteristics on soil erodibility. Small plots are much easier to prepare; however, the edge effect from plot boundaries may affect research results. The edge effects associated with small plots include the splash in and out of the plot perimeter as well as the drainage of the soil water from the bottom of the plot.^[13]

For small plot erosion study, it is necessary to retain a border area around the perimeter of the plot so that the splashed soil in and out of the plot can be compensated. As far as the bottom boundary of the small plot is

concerned, an open bottom made of screen is often used to provide a free drainage condition.

Careful arrangement of the storm sequence is necessary in simulated rainfall studies to replicate the effect of a natural storm pattern and antecedent soil–water contents on soil erodibility. Therefore, it is always a good practice to have field-measured soil erodibility data to correlate with simulated rainfall erodibility results.

Rainfall Simulators

A rainfall simulator is a common tool used for water erosion research. It greatly reduces the time span of erosion study, and it is more controllable than natural rain. It also provides researchers the means to repeat the study anywhere and anytime they wish.

The basic requirement for a rainfall simulator is to produce rainstorms with drop size distribution, impact velocity, and intensity similar or close to those of natural storms.^[14] Numerous types of rainfall simulators have been developed for erosion study. Rainfall simulator can be mobile for field study, and it can also be housed in a building. Two types of raindrop-forming techniques are commonly used, namely nozzle-type and free-fall-type.

The nozzle-type rainfall simulator generates simulated rainfall by forcing water through a spray nozzle to increase the drop velocity, so that as simulated rainfall reaches erosion plot, the impact velocity can reach that of the natural rain. On the other hand, the free-fall-type simulator generates rainfall by forming waterdrops from a matrix of hypodermic needles. Therefore, it requires greater fall height for drops to reach terminal velocity. The raindrop generator shown in Fig. 1 is housed in a 15-m-tall rainfall simulator building with an effective fall height of 11 m. This rainfall simulator has an effective working area of 3 m × 4 m, as shown in Fig. 2, with a manual and automatic control for desired rainfall intensities. Users can feed the rainfall

Fig. 1 Free-fall-type raindrop generator.

Fig. 2 Adjustable working platform for erosion research.

simulator with a rainstorm histogram so that the history of a storm can be simulated.

Extending the results generated from rainfall simulator studies to erosion under natural rains can be difficult. Water erosion at field conditions is affected not only by rain characteristics and soil's dynamic behavior but also by cropping and land management practices that from time to time cannot be effectively quantified under rainfall simulation environment. Hence, one needs to recognize the differences between simulated and natural environments.

Plot Design and Layout

Erosion plots are often laid out with different widths and lengths to meet various research objectives. Rill erosion seldom occurs on slope length less than 5 m with gentle slope steepness;^[13] however, rilling has been commonly observed on steep slopes with slope length less than 5 m, such as newly constructed embankments along the roadways. Therefore, researchers use different plot layouts to meet their specific needs.

Interrill Erosion

Interrill erosion is mainly caused by raindrop impact. It is less noticeable than other forms of erosion. Researchers have been using small plots 0.5–1 m long along with rainfall simulators to quantify interrill erosion. The measurement technique adapted for interrill erosion study is quite simple—by sampling sediment concentration or sediment load and runoff volume at the downstream end of a small plot.

Rill Erosion

Rill erosion is a common erosion process on longer slope lengths and/or steeper slopes. It often produces greater amount of sediment; therefore, H-flume as well as auto-sampler may suffer the sedimentation problem during sample

Fig. 3 Coshocton wheel sampler.

collection. An H-flume^[15] with a calibrated stage recorder can be attached at the outlet of runoff plot to obtain the runoff hydrograph, whereas an auto-sampler like Coshocton wheel sampler (Fig. 3) can be used to acquire sediment concentration histogram. However, due to high sediment concentration, H-flume as well as auto-sampler may suffer the sedimentation problem during sample collection.

There are more options of plot design to choose from to study the effects of slope length and slope steepness. One option is to set up runoff plots at various slope lengths and slope steepness. The research site shown in Fig. 4 was located on a 60% steepness slope. Due to land limitation, runoff plots were divided into segments along the slope using grass buffer and drainage ditches to complement the desired slope lengths.

Another option to quantify the slope steepness effect is to use soil boxes with adjustable slopes (Fig. 5). At the downstream end of a soil box, collection trough and sampling buckets are often used to collect lumped samples. H-flumes, stage recorders, and auto-samplers can be used to obtain continuous samples.

The added-inflow technique^[16] is an alternative to simulate long slope length condition. The technique basically consists of inflow pipe, flow rate regulator, and a damping

Fig. 4 Sixty percent steepness erosion research site.

Fig. 5 Erosion research conducted using soil boxes on a slope-adjustable platform.

device. The purpose of the damping device is to prevent inflow from scouring the soil bed at the flow entrance, which may constitute a greater portion of sediment in the sample. The amount of inflow added to small runoff plots depends on the slope length that a researcher wants to simulate. It requires runoff hydrographs generated from short slope lengths at otherwise identical experimental conditions.

For those only interested in total runoff and soil loss, a set of stilling tanks with sample splitters installed at the rims of tank walls is probably the cheapest way to achieve the objective (Fig. 6). As the main sediment stilling tank is filled with sediment and runoff, the splitter can split the excess runoff in a desired portion into the second tank and so forth.

Cover/Management and Support Practices Factors

The effects of cover/management and support practices on soil erosion require erosion study on larger scales because all these controlling factors affect runoff routing, surface roughness, and sediment delivery, which are difficult to

Fig. 6 Stilling tanks and runoff splitters.

capture on small plots. Hence, rainfall simulator studies resulting from small plots may not unveil the actual physical processes occurring at large scales. In such case, a pair of gauged watersheds is probably the most suitable technique to choose. One watershed is treated with selected management or practices, and the other serves the sole purpose of comparison. In the case of watershed study, collection trough and stage recorder are usually used.

As far as the measurement of sediment outflow is concerned, auto-samplers, Coshocton wheel samplers, or a set of stilling tanks will serve the purpose. However, Coshocton wheel samplers as well as auto-samplers require undivided attention to ensure that devices are operational. A motor may be needed to drive Coshocton wheel sampler to guarantee free rotation of the sampler especially during low flow. For sites that having high potential of yielding coarse sediment, clogging at the sample vane of Coshocton sampler as well as at siphon tube intake may cause problem.

OTHER MEASUREMENT TECHNIQUES ASSOCIATED WITH WATER EROSION ASSESSMENT

Aerial photographs taken at different times can be used to assess the occurrence of erosion, progress of gully erosion processes as well as mass movement. It can also assess the effectiveness of erosion control qualitatively. Using aerial photographs with geographic information system helps identify erosion hot spots on large-scale areas that may not be easily visualized from ground survey. Nevertheless, thorough ground survey is needed to quantify the volume of gully erosion.

If the progress of rilling is the main subject of the study, a rill meter (Fig. 7) or laser profiler^[17] is a convenient tool. Geometry of the rills can be photoed manually or scanned automatically transaction by transaction and analyzed digitally. However, natural consolidation due to soil wetting and compaction caused by raindrop impact may affect the surface profile readings. Therefore, quantification of soil

Fig. 7 Rill meter.

loss volume using profile scanning may require additional adjustment.

Collecting sediment concentration samples from a stream or river channel is another option for qualitative erosion assessment. One needs to be cautioned on the interpretation of stream or channel sediment data. Sediment samples collected from a river channel are actually the product from upland erosion, sediment delivery along the basin, and erosion initiated from stream banks. There is no certain means to distinguish the source of sediment.

CONCLUSION

Erosion measurement techniques vary widely in scale, time, and cost involved, and there is no standard procedure to follow. Different methodologies produce different results. Researchers need to make their own judgments to select the most feasible methodology to ensure that the research objectives are addressed. A proper understanding of the quality of data associated with specific erosion measurement technique will result in useful information for the erosion research.

Erosion: Perennial Crop Plantations

Alfred E. Hartemink

International Soil Reference and Information Centre (ISRIC), Wageningen, the Netherlands

Abstract

It is generally assumed that a perennial tree cover protects the soil better against erosion than do annual crops. But tree crops may require several years to close their canopy, whereas most annual crops provide adequate cover within 6 weeks after planting. During the immature phase of tree crops, there may be insufficient soil cover. The effects of tree crops on soil erosion have been fairly well documented. Soil erosion and sediment transport from catchments with natural forests are minimal (<1 Mg/ha/yr), but the levels of soil erosion tend to increase when the natural forest is changed to tree crop plantations. Considerable differences have been found between crops and sites, and much depends on the soil, site factors (slope, rainfall, etc.), and management practices. In this entry, the main findings for oil palm, coffee, cocoa, and tea plantations in tropical regions are reviewed.

INTRODUCTION

Plantation agriculture is an important form of land use in the tropics. Large areas of natural and regenerated forest have been cleared for growing oil palm, rubber, cocoa, coffee, and other perennial tree crops. These crops grown both on large-scale plantations and by smallholders are an important source of income for many farmers in tropical regions.

EROSION UNDER OIL PALM

Several soil erosion studies under oil palm have been conducted in Malaysia (Table 1). Soil erosion from Oxisols ranged from 13 to 78 Mg/ha/yr and depended on the slope of site. Soil erosion on Ultisols ranged from 1 to 28 Mg/ha/yr, and the erosion was higher in harvesting paths. In mature oil palm plantations, soil erosion losses chiefly depend on the slope of site and soil management practices. Under young oil palm, soil erosion is usually limited because of the cover crop protecting the soil, and the limited erosion is not attributable to the palms. This was also reported from rubber plantations (Fig. 1).^[1] As the cover crop disappears after the closure of the palm canopy, harvest paths become exposed and compacted which enhances runoff and soil erosion. Therefore, soil erosion may not necessarily decrease when the palms get older and the canopy is closed. Chew, Kee, and Goh^[2] reviewed and published soil erosion data for moist forest and tree crop systems. Erosion under mature oil palm ranged from 7 to 21 Mg/ha/yr. These values are lower than those reported in Table 1, but the review showed that soil

erosion could be considerable at oil palm plantations in Malaysia.

The effects of erosion under oil palm are that the soil is removed from between the tertiary and quaternary feeding roots near the soil surface, in particular in the weeded circle. Exposed roots dry up and die, so that the water and nutrient uptake capacity of the root system is reduced. Although no experimental evidence is available, it is obvious that oil palms growing under these conditions undergo water deficits and nutritional deficiencies.^[3] Moreover, the nutrient use efficiency of applied fertilizers is reduced because of the lower uptake capacity of the roots.

EROSION UNDER COFFEE AND COCOA

Soil erosion losses can be considerable in coffee plantations that have no adequate shade or a low planting density with little natural mulch formed by litter. This is especially important for coffee grown in highlands on steep slopes and in new coffee plantations. Research in Colombia showed that annual soil nitrogen losses from unprotected areas exceeded the amount extracted by a good crop of coffee, but on well-developed coffee plantations that are adequately shaded or with a high planting density, erosion can be reduced to less than 2% of the losses that occur on unprotected plots.^[4]

In Venezuela, where since the mid-1970s the government has actively promoted the removal of shade trees from coffee plantations, low erosion losses were found.^[5] Under shaded coffee, total erosion losses were very low and less than 2 Mg soil/ha/yr, whereas under coffee

Table 1 Soil erosion losses under oil palm in Malaysia.

Soil order	Palm age (years)	Slope (%)	Condition	Soil erosion (Mg/ha/yr)
Trophectic Hapludox (Oxisols)	2–4	2	With legume cover crop	18.8
		5	With legume cover crop	24.0
		9	With legume cover crop	35.4
		15	With legume cover crop	50.0
Typic Hapludox (Oxisols)	2–4	12	<5 Uncovered	12.5
		2	With legume cover crop	23.5
		5	With legume cover crop	38.8
		9	With legume cover crop	57.1
Orthoxic Tropudult (Ultisols)	11	5	With legume cover crop	77.6
			Harvesting path	14.9
			Palm row	7.4
Typic Paleudult (Ultisols)	12–16	3–5	Beneath row	1.1
			Uncovered	28.0
			Plots with fronds cut	19.7
			Plots with extra fronds cut	16.3

Source: Adapted from PORIM^[12] and Hartemink.^[13]

without shade, erosion losses were 7 Mg soil/ha in the first year after the shade was removed. Erosion losses of unshaded coffee after 2 years were comparable to that of shaded coffee, whereas in general runoff and soil loss are lower in shaded than in unshaded plantations.^[6] The research in Venezuela showed that soil erosion correlated positively with agricultural activities (i.e., harvesting, pruning, and weeding).

Under monocropping cocoa in Malaysia, soil erosion losses were 11 Mg/ha/yr, but losses were considerably lower when cover crops such as *Indigofera spicata* were planted.^[7] When the cocoa was intercropped with banana, and clean weeding with herbicide was practiced, soil losses up to 70 Mg soil/ha/yr were measured, which are high losses based on a general rating of tolerable soil erosion losses.^[8,9]

EROSION UNDER TEA

In mature tea plantations, erosion is negligible (Fig. 2) because of the complete soil cover. Some soil erosion may occur directly after pruning and when the prunings

Fig. 1 Young rubber trees with cover crop in North Sumatra.

are removed. Othieno^[10] reported from Kericho (Kenya) erosion losses up to 168 Mg soil/ha in the first year after the establishment of a tea plantation. In the second year, soil losses were up to 81 Mg/ha, whereas in the third year losses were less than 7 Mg soil/ha. Three-quarter of the total erosion over the three-year period of the experiment occurred between planting and the time when the canopy had developed to 30%. Soil erosion can also be a problem when plantations run down. This was found to occur in Sri Lanka where tea plantations have been neglected since the mid-1970s, causing serious soil erosion of vacant patches.^[11]

THE EFFECTS OF SOIL EROSION ON SOIL CHEMICAL PROPERTIES

The on-site and off-site effects of soil erosion are well documented. In tropical regions where many soils suffer from an inherent low fertility that is mostly concentrated in the topsoil, loss of topsoil by soil erosion means a serious reduction in soil chemical fertility.^[15–17] Moberg^[14] compared soil fertility properties of Oxisols developed from sandstone in eroded and non-eroded coffee plots and in virgin land near Lake Victoria, Tanzania. Coffee gardens where erosion occurred were more acid and had lower levels of soil fertility than non-eroded soils with coffee, the levels of which were comparable to virgin soils (Table 2).

EROSION CONTROL

Soil erosion is likely to occur during land preparation and when the tree crop is immature, but several well-established measures exist and are being used. On oil palm plantations, soil erosion is commonly checked by early cover crop establishment, strategic placement and treatment of pruned fronds, and old palm trunks with felling, terracing, the construction of silt pits, and mulching with empty fruit bunches.^[12] Research in Kenya indicated that soil erosion in fields with young tea can be effectively controlled by either mulching or interrow planting of oats although oats may compete with young tea for water and nutrients.^[10] In general, cover crop establishment and terracing sufficiently control erosion in tree crop plantations in tropical regions.

CONCLUSION

Soil erosion under perennial crops is relatively low, provided the crops are well managed.^[13] Measured data show that erosion could be high in oil palm,^[12] cocoa,^[7] and tea^[10]—particularly during establishment or when plantations are neglected. Agroforestry research has

accumulated considerable evidence confirming lower erosion in land use systems with tree crops than with perennial plantation crops.^[18,19] The available data confirm that soil erosion is lower in land use systems with perennial crops than under annual cropping: land use systems with perennial crops form better protection against soil erosion than annual crops simply because they cover the soil throughout the whole year. The risks of soil erosion under plantation crops differ among crop species depending on their canopy characteristics and soil management system.^[20,21] As soil erosion affects the soil chemical fertility, the fertility of the soil should be taken into account when interpreting erosion losses. In general, tolerable losses from acid and poor fertility soils should be appraised much lower than losses from inherently fertile soils.

Erosion: Sedimentation Control Amendment Techniques

X.-C. (John) Zhang

Grazinglands Research Laboratory, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), El Reno, Oklahoma, U.S.A.

Abstract

Any material that is added to soil to benefit the soil or plant is called a soil amendment. A closely related term to soil amendment is soil conditioner. Soil amendments are either incorporated into the soil or applied on the surfaces. Soil amendments, such as animal waste, farmyard manure, green manure, crop residues, and composts, have been used for many centuries to recycle plant nutrients and to improve soil structure and tilth. Crop residues, preserved by no-till and conservation tillage, have been widely used to reduce soil erosion. Due to increasing landfill costs, applications of municipal and industrial wastes and by-products to agricultural lands have increased dramatically in past decades. Further, interests in using synthetic polymers to reduce water runoff and soil erosion have been revived. All these soil amendments have beneficial effects on the physical, chemical, and biological properties of soil and, therefore, on plant growth. Most amendments are effective in reducing soil erosion by water, although only a few are effective in controlling erosion by wind.

INTRODUCTION

Any material that is added to soil to benefit the soil or plant is called a soil amendment.^[1] For example, lime, gypsum, animal manure, green manure, sewage sludge, compost, crop residue, woodchips, leaves, sawdust, synthetic polymers, and industrial waste such as paper sludge are all soil amendments. Soil amendments, though arbitrary, may be grouped by their origins into five different categories (Table 1). Technically, chemical fertilizers are soil amendments, but conventionally they are not referred to as such. A closely related term to soil amendment is soil conditioner. A soil conditioner is a substance that has the ability to improve the physical condition of a soil for better aeration, water-holding capacity and infiltration, porosity, structural stability, erodibility (susceptibility to erosion), and tilth. Actually, soil conditioners are also soil amendments that are used to create favorable physical environments for plant growth.

Soil amendments are either incorporated into the soil or applied on the surfaces. Incorporated materials ameliorate soil properties, while surface-applied materials mostly affect the atmosphere–soil interface. Soil amendments, such as animal waste, farmyard manure, green manure, crop residues, and composts, have been used for many centuries to recycle plant nutrients and to improve soil structure and tilth. Crop residues, preserved by no-till and conservation tillage, have been widely used to reduce soil erosion.^[4] Due to increasing landfill costs, applications of municipal and industrial wastes and by-products such as sewage sludge, paper mill sludge, wood products, and gypsum to agricultural lands have increased dramatically in past decades.^[5] Interests in using synthetic polymers to

reduce water runoff and soil erosion have been revived. All these soil amendments have beneficial effects on the physical, chemical, and biological properties of soil and, therefore, on plant growth.^[1,4,5] In relation to erosion control, most soil amendments are effective in increasing soil aggregation and soil structural stability,^[6] decreasing erosive forces of raindrop impact and flowing water, reducing surface crusting (a thin, dense surface layer with very low water permeability), and improving water infiltration. These beneficial effects not only reduce soil erodibility but also rainfall-runoff erosivity. Thus, most amendments are effective in reducing soil erosion by water, although only a few (e.g., standing residue cover) are effective in controlling erosion by wind.

TYPES OF SOIL AMENDMENTS

Lime

Liming materials such as quicklime (CaO) and limestones are the most widely used mined or mineral soil amendments. Liming soil has a long history in the United States. Early settlers started to lime soil from the beginning of the 19th century. By the early 20th century, liming had become a routine agricultural practice to raise soil pH and increase crop productivity. Liming soil generally improves the physical and chemical properties of soil^[1,7] by neutralizing soil acidity, reducing phyto-toxicity of aluminum (Al), manganese, and hydrogen ions, increasing plant availability of many nutrients, promoting microbial activity, and increasing clay structural stability. However, over-liming can result in clay dispersion and aggregation disintegration in

Table 1 Type and example of commonly used soil amendments.

Type	Example
Mined or mineral	Lime, gypsum
Synthetic polymer	PAM
Manure and compost	Animal manure, green manure
Mulches	Crop residue, woodchips
Municipal and industrial wastes	Sewage sludge, paper mill sludge

Source: From Zhang & Miller.^[2,3]

highly weathered, high Al^{3+} soils. Beneficial effects of liming on soil erosion result from reduction of soil erodibility because of improved soil aggregation and structural stability and increase of surface cover due to enhanced plant growth. Lime has also been successfully applied as a stabilizer and cementing agent to control side sloughing of canal embankments and pipe erosion on earthen dams, which are composed of highly dispersive and expansible clays.^[1,8]

Gypsum

Gypsum (mined or industrial by-products) has been widely used for many decades to ameliorate unstable, high sodium (Na) soils (e.g., sodic soils). In years, research has demonstrated that soils with low Na and electrolyte concentration (EC) can also be dispersive, and gypsum addition is effective in reducing surface sealing and crusting, increasing water infiltration, and reducing soil erosion by water.^[9,10] The beneficial effects of gypsum addition on soil erosion reduction result from increased soil aggregation and structural stability due to elevated EC in soil solution and the predomination of calcium ions on the exchange sites. Cation valence and EC are two major factors influencing clay behavior, i.e., clay flocculation or dispersion.^[11] When two clay particles approach each other, their electric double layers (a negatively charged clay surface surrounded by a compensating cation cloud) begin to overlap or repel each other. The cation cloud is pushed toward the particle surface when EC is increased or when a divalent cation replaces a monovalent cation. The reduction in the cloud thickness results in a decrease in this repulsive force. When a critical EC is reached, at which the van der Waals attractive force overcomes the repulsive force, rapid coagulation takes place. This concentration is termed critical flocculation concentration (CFC). It should be pointed out that cation valence has a dominant effect on clay flocculation. This is the reason for using Al salts, such as Alum, to flocculate suspended particles in many water-treatment plants. Among the common soil cations (e.g., Al^{3+} , Ca^{2+} , Mg^{2+} , K^+ , Na^+ , and H^+), Ca^{2+} has the greatest flocculation power excluding Al^{3+} (which is only significant in acid soils), while

Fig. 1 Flocculation test series after 6-hour settling using Cecil soil clay. (From left: 0, 2.5, 5, 10, and 15 mmol_e gypsum/L).

Na^+ has the least. This is why sodic soils have poor soil structure and gypsum addition helps to improve it. On the basis of this theory, clay particles flocculate when EC is greater than CFC, otherwise dispersion takes place. Clay flocculation is clearly shown in Fig. 1. After 6-hour settling, more dispersed clay particles have coagulated into microaggregates and settled at the bottom as gypsum concentrations increase from left to right. Clay flocculation promotes soil aggregation and structural stability, while clay dispersion often leads to deterioration of soil structure, partially because clay is one of the primary cementing agents for soil aggregation. Increased soil aggregate stability decreases soil erodibility, improves water infiltration, and reduces soil erosion by water.^[1,9,10]

Synthetic Polymer

Synthetic polymers with various charge and chemical properties have been used to improve soil physical properties. In early studies, polymers were typically

Fig. 2 Soil aggregates of a Miami silt loam soil both without (left) and with (right) an anionic PAM treatment after exposure to a simulated rainfall event.

Table 2 Effects of gypsum, anionic PAM, and canopy cover on water infiltration and soil loss in a Cecil sandy loam soil during an initial 31-minute simulated rain at an intensity of 88/mm/hr.

Treatment	Total infiltration (mm)	Percent runoff (%)	Erosion rate (kg/m ²)
Untreated	20.5	54.7	1.63
Canopy cover	27.2	39.9	0.67
Gypsum	26.5	41.4	1.13
PAM	43.2	4.5	0.01

incorporated into the entire plow layer to promote structural stability and water permeability. The enthusiasm reached its peak in the 1950s upon reports that polymers were effective in reducing erosion, improving water infiltration, and increasing crop yields. However, the enthusiasm was subdued by high cost and large quantities needed to amend deep soil layers. In years, interest has been revived by new polymer products and new application strategies. Only a small amount of polymer, when sprayed on the soil surface or dissolved in irrigation water, can reduce surface seal and crust formation and, therefore, reduce runoff and soil erosion.^[1] Surface sealing, formed by disintegration of soil aggregates and dispersion of clay particles, causes extremely low water permeability. The threadlike large polymer molecules or interwoven polymer nets are strongly (often irreversibly) adsorbed by soil aggregates and clay particles. The adsorbed polymer nets that surround soil aggregates physically protect them from disintegration by raindrop impact or shear force imparted by flowing water. This is shown in Fig. 2, where soil aggregates, which have been treated with an anionic polyacrylamide (PAM), are more stable than untreated aggregates after exposure to a 65-mm/hr rain for 10 minutes. Polymers can also chain clay particles together to promote flocculation. Polymers have been used to flocculate clay

particles in sedimentation ponds. For anionic polymers, the effectiveness is usually improved by adding an electrolyte, such as gypsum, because cations are basic ingredients for building cation bridges between negatively charged clay platelets and polymer molecules. Because of the ability to stabilize soil aggregates and improve soil structure, polymers are effective in controlling surface seal and crust formation, increasing water infiltration, and reducing soil erosion. Polymers have also been successfully used to control soil erosion on steep slopes on construction sites and road banks.

Manure, Compost, and Organic Sludge

Animal, farmyard, and green manures have been used as organic soil amendments to improve soil productivity for many centuries. In years, application of municipal biosolids (sewage sludge) and industrial waste compost such as paper sludge to agricultural lands has increased dramatically. These materials have the ability to increase aggregate stability, porosity, and water-holding capacity, reduce runoff and erosion, improve soil tilth, increase plant nutrient availability and soil cation exchange capacity, and elevate soil microbial activities.^[9] Decomposed organic substances such as humus along with soil clays are primary binding agents for soil aggregation. An increase in soil organic matter content often leads to increased soil aggregation and structural stability. Thus, the addition of organic materials such as manure and compost can reduce soil erosion by water by improving soil aggregation and reducing runoff volumes. In addition, improved soil conditions enhance rooting and plant growth, which increases plant cover and root biomass that further reduce soil erosion. It should be pointed out that substantial rates of application over time are needed to considerably increase soil humus levels.

Fig. 3 Rill development and surface conditions of four surface treatments (from left: untreated, 5/Mg/ha gypsum, screen canopy cover, and 15/kg/ha PAM) after exposed to an 88-mm/hr rain for 31 minutes (soil: Cecil, sandy loam; plot size: 3.5 by 0.9/m; slope: 11%).

Mulches

Most mulch materials used for runoff and erosion control are naturally occurring soil amendments. Both inorganic and organic mulches have been used. Inorganic mulches include stone, gravel, sand, and many others, while organic mulches are normally undecomposed materials derived from living matters such as crop residue, hay, leaves, woodchips, and sawdust. These materials dissipate raindrop impact energy, protect surface soil aggregates from disintegration by raindrop impact, prevent surface seal formation, reduce raindrop-impact-induced turbulence, obstruct overland flow, and enhance water infiltration. These processes not only reduce soil detachment by raindrop impact but also suppress sediment transport by thin overland flow. Therefore, surface mulches are very effective in reducing surface runoff and soil erosion by water. Many studies have shown that both runoff volumes and soil loss rates decrease rapidly (often exponentially) with increase of surface mulches.^[4,12,13] Buried or incorporated residues are also effective in reducing soil erosion, especially rill erosion (erosion by concentrated overland flow in small channels). However, the reduction is generally less as compared to surface residues. Moreover, organic mulches eventually decompose into humus and impart to the soil all the beneficial qualities derived from traditional organic matter additions as discussed earlier.

CONCLUSION

An example from field studies^[2,3] is summarized in Table 2 to illustrate the general effects of soil amendments on erosion control. Compared with an untreated plot, the canopy cover, gypsum, and PAM treatments were all effective in reducing runoff and erosion. In this example, PAM was the most effective treatment followed by the cover treatment. This was also illustrated by the surface conditions in Fig. 3. A rill was fully developed in the untreated plot during a 31-minute rain; however, only a small rill was initiated in the gypsum plot, and no rill incision occurred in the cover and PAM plots. Also, the resultant surface conditions differed among different treatments. A smoother surface, on the untreated and the cover

plots, indicates disintegration of soil aggregates and seal/crust formation. In contrast, a well-aggregated, rough surface was exhibited on the PAM plot. This explains why almost all rainfall water has infiltrated into the soil on this plot. In general, the effectiveness of these treatments declined with time and the treatment longevity varied from weeks to months. To maintain the effect, PAM and gypsum must be reapplied at some intervals, which depend largely upon soil and environmental conditions.

Erosion: Sedimentation Control Vegetative Techniques

Samson D. Angima

Oregon State University, Corvallis, Oregon, U.S.A.

Abstract

Soil detachment and erosion occur when soil is disturbed by either human activity or natural conditions such as extreme weather. As a result of this, the soil is moved from one point to another by either wind or water. Practices such as road construction, suburban and industrial developments, stream channel and other types of construction on sloping lands, inadequate drainage facilities, poor grading practices, deforestation, cultivation on sloping lands, and general lack of adequate planning by land users cause soil erosion. Consequences of soil erosion include water and air pollution, reduced land productivity from loss of topsoil and nutrients, and degradation of the environment. Soil erosion by water is controlled mainly by earthworks and engineered constructions such as terracing aimed at reducing the slope and at collecting and storing moisture while reducing runoff to acceptable limits. Vegetative barriers are grass, shrubs, and small trees grown in close rows that can be used to control both water and wind erosion by providing protection from soil and dislodging sources such as rainfall and offering a semipermeable barrier to erosion agents resulting in soil deposition. The resultant vegetation also shields the soil surface from overland flow and decreases the erosive capacity of water flow by reducing its velocity.

VEGETATIVE MATERIALS FOR SOIL EROSION AND SEDIMENTATION CONTROL

Vegetative cover is essential for the design and stabilization of many structural erosion-control devices (Fig. 1). Proper vegetative cover provides excellent erosion protection and sedimentation control. Vegetative barriers are planted in close rows along contours on slopes to intercept water runoff or are planted perpendicular to the direction of wind to retard wind movement, resulting in soil deposition. Plant roots and lateral stems provide a structure to hold soil particles in place. These features also improve the soil's physical properties and increase infiltration rate, thereby decreasing runoff. Plant transpiration reduces soil moisture levels, which increases soil absorption capabilities. Not every plant material can serve as a soil erosion-control agent. Those plants that possess some bioengineering characteristics in both the root and the shoot systems that encompass both living plants and organic materials as construction elements for erosion control. Such properties include noncompetition with adjacent crops or fruit trees for moisture or nutrients, a rooting system that reaches deep down to anchor the plant and also extract leached nutrients from the subsoil and shade tolerance. The plants must be perennials with high seed vigor, have the ability to increase soil organic matter and to reduce surrounding soil bulk density to allow faster water infiltration, and have strong woody stalks to withstand pressure from erosive agents.

Vegetative materials used for soil erosion control include grass species, legumes, trees, shrubs, vetches, and sods. Common grass species that bunch during growth

include Tall fescue, Perennial ryegrass, Orchardgrass, Timothy, Switchgrass, Weeping lovegrass, Deertongue, and Big bluestem. Bunching legumes include birdsfoot trefoil and Sericea lespedeza. Cereals such as winter wheat, winter rye, spring oats, Sudangrass, and Japanese millet are also used. Sod-forming species include grasses such as redbud, fine fescue, Kentucky bluegrass, smooth brome-grass, and legumes such as crownvetch and flatpea.^[1] Shrubs and small trees that are used as barriers in erosion control include *Calliandra calothyrsus*, *Sesbania sesban*, *Leucaena leucocephala*, *Gliricidia sepium*, *Cassia siamea*, *Eucalyptus* spp., *Casuarina* spp., *Acacia* spp., *Azadirachta indica*, and *Grevillea robusta*.^[2] Tree species selection depends on local land use and climatic conditions that favor establishment.

MASS PLANTING OF VEGETATIVE COVER

Mass planting of vegetative cover is done where land that is susceptible to erosion is converted from cropland to vegetative cover such as in the conservation reserve program. In this program, trees as well as sods are planted in strategic places, where they will provide maximum protection to the soil resource, and the landowner agrees to leave the areas under vegetation for a given period of time for land stabilization to occur. The vegetative cover also reduces water pollutants such as fertilizer nutrients, pesticides, and herbicides in the runoff water, increases oxygen levels, reduces greenhouse gases and evaporation rates, and provides shade and buffers against high winds.^[2]

Fig. 1 Vegetative barriers/strips hold the terraces intact for agricultural production in Kabale, Uganda.

Source: Photo courtesy of Samson Angima.

VEGETATIVE STRIPS

Vegetative strips constitute different types of filter strips that reduce runoff velocity and provide differing degrees of filtering action depending on the species used. Larger soil particles tend to settle out readily, leaving only clay particles suspended and thereby reducing pollutant transfer to ponds, rivers, and lakes. Filter strips can be classified as grass strips, vegetated waterways, filter strip terraces, buffer and riparian strips, and settling basins.^[3]

Grass Strips

Grasses are by far the most important vegetative materials used to control erosion. Bands of grass about 1–2 m in width are planted along the contours and spaced every 10–100 m depending on the slope (Fig. 2). Prior to planting, the land is roughened by disking, harrowing, or raking and then limed, fertilized, and seeded with mixtures of adapted grasses and legumes to enhance a good stand.^[4] Vetiver grass (*Vetiveria zizanioides*), Napier grass (*Pennisetum purpureum*), and Stiff grass (*Miscanthus sinensis*) are the most commonly used species.^[2] These are upright, tufted, deep-rooted, and very dense grasses that are by far the most important in erosion control, particularly in tropical countries. Vetiver is a bunch grass with very rapid growth in warm and moist conditions. It grows to more than 2 m in height and has a remarkably dense and vertical rooting system, growing deep (3–5 m). Napier grass is a tall perennial reaching over 3 m high. It is resistant to drought and grows at altitudes up to 2400 m. Stiff grass has dense roots and coarse stems that withstand erosive agents. These grass hedges present a virtually impenetrable barrier through which soil can hardly pass and only water, with much reduced velocity, passes.^[5] As silt builds up behind the grass, other grass shoots arise from the nodes above the

Fig. 2 Schematic sketch of vegetative barriers illustrating expected change in land slope over time resulting from tillage and erosion deposition process.

deposited silt to form a natural terrace. Weeds and undesirable foreign grasses are unable to penetrate through a well-established grass hedge. Studies carried out in Mississippi, using stiff grass (*M. sinensis*) on no-till and conventional tillage,^[6] showed that grass strips help reduce sediment losses by up to 88% on conventional tillage and 57% on no-till cotton plots (Table 1). Other grass species include Buffalo grass (*Buchloe dactyloides*), grama or mesquite grasses (genus *Bouteloua*), Switchgrass (*Panicum virgatum*), and *Phalaris aquatica*.

Vegetated Waterways

Vegetated waterways are channels or waterways that transfer runoff from a higher to a lower elevation over a short distance without allowing erosion to occur (Fig. 3). In addition to dissipating flow energy, some structures also act to retain soil. They are especially effective in arresting gully development, a situation that might need both structure(s) and some vegetated channels. They have many uses in comprehensive conservation plans, but they primarily collect and concentrate flows and then safely transport the water to major drainage systems. Dense vegetation is used to minimize the area required, i.e., the protective action of the vegetation permits higher flow velocities and thus smaller waterway cross sections. Most vegetated waterways run directly down a slope; however, they can also be constructed somewhat across the slope as diversions or sometimes just to reduce channel slope. Vegetated channels are not used where continuous flow occurs because the vegetation will die out. Tillage near a waterway is accomplished in a direction across the waterway. Sod-forming, cool-season grasses such as smooth brome or Western wheatgrass are used in grass waterways. Grass waterways are usually designed to carry runoff of a 24-hour storm of the intensity that happens once every 10 years. In areas with

Table 1 Sediment loss with and without grass strip (*M. sinensis*) under no-till and conventional tillage cotton at 5% slope.

Period	Sediment loss (t/ha)				
	No-till with grass strip	No-till without grass strip	Conventional tillage with grass strip	Conventional tillage without grass strip	No-till with winter wheat cover
1992	2.6	4.5	12.3	60.3	2.9
1993	0.9	1.6	5.4	21.9	1.2
1994	3.2	9.6	18.6	63.2	1.9
Average	2.2	5.2	12.1	48.5	2.0

Source: From McGregor, Dabney, et al.^[6]

prolonged water flows, high water tables, or seepage problems, a rock-lined center is added.^[1]

Filter Strip Terraces

Filter strip terraces are strips of grass sod, legumes, and other vegetation on the contour that surface water runoff crosses as it runs downhill. They serve as an alternative to earthen terraces but do not have a channel to conduct water along the contour, as earthen terraces do. Filter strip terraces are excellent removers of sediment, pesticides, organic matter, and other pollutants. They are better than grass waterways because water enters the strip uniformly and over a wide area.^[3] The width and type of vegetation established in the filter area are determined by site conditions including soil type, land slope, and the type of runoff entering the filter.

Small trees and shrubs are also used as conservation hedges in erosion control. These are planted close together and are periodically pruned to maintain height while the cut branches are inserted upslope of the hedge to trap more sediment. Trees that have been used successfully in erosion control, especially in agroforestry systems in the tropics, include *C. calothyrsus*, *S. sesban*, *L. leucocephala*, *G. sepium*, and *C. siamea*. Trees used for windbreaks

include *Eucalyptus* spp., *Casuarina* spp., *Acacia* spp., Neem tree (*A. indica*), and *G. robusta*.^[7] In the temperate zone, thorny hedge plants include barberry, Osage orange, buckthorn, and hawthorn. Evergreen hedge plants are box, privet, azalea, yew, arborvitae, rhododendron, mountain laurel, and holly.^[8] Decorative deciduous shrubs often used are lilac, forsythia, mock orange, Spiraea, euonymus, and viburnum. *Rosa rugosa* can be planted along the highway embankments, and rows of poplars, hemlocks, and other trees can be used as shelterbelts. Vegetative or biological measures may include log bundles anchored to the stream bank or the planting of herbaceous or woody plants, which can withstand high velocity flow, while the roots form a protective net for the soil.

Buffer Strips and Riparian Strips

Buffer strips at lower elevations of fields (Fig. 4) and riparian strips along stream banks, ponds, and lakes (Fig. 5) intercept surface runoff water from crop fields. Buffer strips may constitute ordinary grassed fencerows or strips of grasses, shrubs, and trees lining hillsides or banks of rivers. Runoff water must flow in a shallow, even layer across the buffer strip to remove sediments. Most common grasses used in buffer strips are Bluestem and Indiangrass. Riparian

Fig. 3 Grass waterways are the most common type of vegetative filter strip.

Fig. 4 Buffer strips at lower elevations of fields intercept surface runoff water from crop fields.

Source: From Regehr, Devlin, et al.^[3]

Fig. 5 Riparian strips along stream banks intercept surface runoff water from crop fields.

Source: From Regehr, Devlin, et al.^[3]

strips are planted so that surface and subsurface runoff must filter through them before it reaches a pond, lake, or stream.^[1] The body of water can be permanent or temporary. Riparian strips can also be placed next to wetlands, such as marshy or swampy areas, and additional vegetation can be placed uphill if excessive amounts of sediments enter the waters.

Settling Basins

Settling basins are constructed around inlets to tile-outlet terraces. These are important in reducing soil sediment loads and also act as setback zones for herbicides such as Atrazine. The basins are designed to retain water for up to 24 hours, giving most of the larger sediments time to settle out.^[3] These are common where tile lines have been installed.

CONCLUSION

Vegetative techniques for erosion and sedimentation control offer a wide range of tools for use by a wide range

of land users especially those that cannot afford engineered or earthen structures. However, for these tools to work well in erosion prevention, they have to be regularly maintained and landowners need to understand that they require time to effectively control enough sediment that can gradually change slope. Research is adding more species of grass and/or shrubs that can be multipurposely used to control erosion and at the same time provide other uses beneficial to the landowner. When used well in conjunction with best management practices, vegetative techniques can substantially contribute to overall water and wind erosion control.

Erosion: Snowmelt

Donald K. McCool

U.S. Department of Agriculture (USDA), Pullman, Washington, U.S.A.

Abstract

This entry reviews winter processes including a range of conditions, from those where the soil freezes and thaws diurnally and is subjected mainly to rainfall, to those where the soil remains frozen for several months and precipitation occurs as snow or in other solid form during all or part of the winter season. In some areas, the soil freezes in the autumn and stays frozen until spring, and the ground is blanketed with snow for the entire winter; erosion is then confined to a period of spring snowmelt. Some areas are subjected to several runoff and erosion events each winter because the winter temperatures and precipitation patterns lead to multiple soil freezing and thawing occurrences with accompanying rain or snowmelt events.

INTRODUCTION

In many areas of the world, winter hydrology is an important part of the annual erosion process; in some regions, it is the primary cause of erosion. Sharratt et al.^[1] indicate that about half of the earth's land surface is frozen at some time during the year. In this topic, we will consider winter processes to include a range of conditions from those where the soil freezes and thaws diurnally and is subjected mainly to rainfall to those where the soil remains frozen for several months and precipitation occurs as snow or in other solid form during all or part of the winter season. In areas where daily minimum temperatures are rarely below 0°C, winter erosion processes are of relatively minor importance as compared to spring, summer, and autumn erosion. At the other end of the spectrum are areas where the soil freezes in the autumn and stays frozen until spring and the ground is blanketed with snow for the entire winter. Erosion is then confined to a period of spring snowmelt. Some areas such as the Palouse region of eastern Washington, northern Idaho, and northeastern Oregon are subjected to several runoff and erosion events each winter because the winter temperatures and precipitation patterns lead to multiple soil freezing and thawing occurrences with accompanying rain or snowmelt events. The result of a particularly severe rain and snowmelt event when the soil had thawed at the surface on a fall-seeded field is shown in [Fig. 1](#).

PRECIPITATION

Precipitation in areas where winter processes are important can occur as rain, or in solid form as sleet or snow. Rain can cause erosion due to splash and runoff detachment, whereas sleet and snow cause detachment by runoff as they melt. In general, winter rainfall intensities are lower than summer rainfall intensities because of the lack of thunderstorm

activity in the winter. However, the frequency and duration of precipitation are commonly greater. As water loss from the soil is considerably lower during the winter due to lower mean temperatures and the absence of actively growing crops, even low intensity rainfall can increase the moisture content of soil rather quickly with a resultant dramatic increase in its susceptibility to erosion. The kinetic energy and intensity associated with rainstorms are not a direct factor in snowmelt erosion. Snowmelt erosion is more closely related to volume and peak rate of runoff, which can be strongly influenced by rainfall when it occurs concurrently with the snowmelt.

SOIL

The phase of the water in the surface layer of the soil is important in the winter erosion process. When soil water is frozen, erodibility, the susceptibility of the soil to erosion, is very low and erosion rates under sheet flow conditions are generally quite low. However, when runoff concentrates in small channels, the flow may cut into and through the frozen layer, leaving gullies and deeply incised channels. Soils that have been frozen and are thawing from the surface are weakened due to water expansion during the freezing process. Lee^[2] cited a number of studies that indicate an increase in water content as water moves to the freezing front from deeper in the soil because the area where the soil is freezing is at very high water tension. The soil will regain strength after the frost has thawed and the soil reconsolidates as water drains from the soil.^[3]

Water content of the soil at the time of freezing is important to the permeability of the soil and the opportunity for infiltration and deep percolation. Lee^[2] found a linear relationship with a negative slope between the ratio of frozen soil infiltration hydraulic conductivity to the unfrozen soil infiltration hydraulic conductivity. Soil frozen at water

Fig. 1 Erosion on fall-seeded winter wheat in eastern Washington caused by rain and snowmelt on thawing soil. Measured rill erosion was 200 metric tons per hectare.

content near saturation is frequently impervious and runoff can be nearly 100% of the rainfall or snowmelt,^[2] thus leading to severe concentrated flow and gully erosion (Fig. 2).

EFFECT OF SNOW AND FREEZING CONDITIONS

During the non-winter period or in climatic regions where winter erosion processes are not a factor, the only type of water erosion that occurs is rainfall on unfrozen soil. Winter erosion is more complex because there are seven basic types of erosion events:

1. Rain on frozen soil;
2. Rain on thawing soil;
3. Rain on unfrozen soil;
4. Snowmelt on frozen soil;
5. Snowmelt on unfrozen soil;
6. Rain on snowmelt on frozen soil; and
7. Rain on snowmelt on unfrozen soil.

Fig. 2 Gully erosion from snowmelt runoff in northern Idaho.

Snowmelt on thawing soil and rain on snowmelt on thawing soil are not listed because, as discussed later, these conditions generally do not occur due to the insulating properties of snow. Further complicating these various types of events is that they typically do not stand alone but occur in some combination and how they combine will dictate the severity of any resultant erosion.

A blanket of snow on the soil surface can have positive as well as negative effects with regard to soil erodibility. Snow is an excellent insulator; the deeper the snow the better the insulation. Thus, a snow layer prior to or concurrent with freezing conditions can retard or prevent frozen soil. However, this insulating property also works extremely well at preventing frozen soil from thawing from the surface down (although thawing will occur in an upward direction due to deeper, warmer unfrozen layers if aboveground temperatures are favorable). Snow cover on frozen soil typically results in the soil surface remaining frozen until bare soil begins to appear as the snow melts with warming temperatures, at which time the exposed soil begins to thaw from the surface down (Fig. 3). The potential for severe erosion can be quite high with the presence of snow and depends on how all the contributing factors come together. If rainfall accompanies the warming temperatures required for snowmelt, runoff can be initiated over the frozen soil beneath the snowpack. If these conditions persist as patches of soil begin to be exposed and surface thawing follows, soil erosion will begin. The nature and severity of the erosion will be determined largely by the intensity and duration of the rainfall and to a lesser degree by temperature that affects the rapidity of the thawing process.

RUNOFF EVENTS

It is difficult to ascribe a single set of characteristics to describe winter hydrology events on hillslopes or small watersheds. Events from rainfall on frost-impacted soil can

Fig. 3 Melting snow exposes bare soil to thaw and increases erodibility.

be of very short duration, whereas events resulting from extended periods of snowmelt can be of much longer duration. Events involving rainfall without snowmelt are usually brief although erosion rates can be high if the soil is thawing from the surface. Events involving snowmelt alone are extended in nature; runoff may fluctuate diurnally as air temperature dips below freezing at night. Erosion resulting from snowmelt alone is generally not severe. The highest runoff rates and flooding result from a combination of rainfall and snowmelt with high air temperatures. As long as the soil is frozen, sheet and rill erosion rates may be quite small, although concentrated flow erosion may be significant. When substantial quantities of bare soil appear, and the soil frost starts to thaw from the surface, erosion rates may increase dramatically. Sediment concentration graphs may lead or lag hydrographs under winter conditions. When there is no snow and the soil has thawed at the surface, a small amount of rainfall may lead to very high sediment concentration that occurs early in the event. When snow melts and the soil is not frozen, the sediment concentration and hydrographs may coincide. When snow melts over frozen soil, there may be little sediment until a portion of the soil is bare and melts. Then the runoff from the melting snow will detach and transport sediment, leading to a significant lag of peak sediment concentration.

MODELING

Erosion models are used to estimate location specific soil losses under various management systems within different land uses. They are also used to estimate expected amounts of sediment and chemicals that may be associated with those sediments. Models may be empirical in nature, such as the universal soil loss equation (USLE)^[4] or the revised universal soil loss equation (RUSLE),^[5] or they may be process based such as WEPP.^[6] The inclusion of winter erosion processes even in empirical models such as USLE or RUSLE complicates the models. Erosion relationships based on runoff characteristics rather than rainfall characteristics may be more appropriate, creating the need to estimate runoff. Process-based models require inclusion of soil freezing and thawing, snowfall and snowmelt, and movement of water into frost impacted soil. Simple soil frost models are driven by air temperature, but more complex models consider radiation and other methods of energy

transfer. It is difficult to strike a balance between excessive data requirement and adequate performance for applied use.

AMELIORATION

Preventing erosion damages from winter processes is similar to preventing erosion damages in other seasons. Cropland and rangeland are best protected by crop and surface cover. Snow collected in standing residue can prevent soil freezing and the creation of an impermeable condition. Surface cover protects from splash detachment, insulates the soil, and slows runoff. No-till practices produce root channels and other pores that enable infiltration when the soil is frozen. Likewise, for areas where frost depth seldom exceeds 30–40 cm, deep ripping, chiseling, or slot mulching to expected frost depth can prevent formation of a continuous frost layer and lead to increased infiltration.

and Environment, Australian National University, Canberra, Australian Capital
Territory, Australia*

Abstract

The prospects for better control of soil erosion have improved in years. Our knowledge of the human and biophysical factors affecting soil erosion has been improved through the use of new methods such as Geographic Information Systems (GIS)-based multiagent modeling; in particular, by locating and targeting erosion hotspots in the landscape, the GIS methods can greatly improve the effectiveness of soil conservation programs. Furthermore, in some developed countries, the elaboration of the concept of multifunctionality of agricultural land will foster approaches and practices that take into account important ecosystem services such as biodiversity protection, landscape integrity, carbon sequestration, and watershed protection. For the developing countries, there have been moves to devise schemes to subsidize the ecosystem services provided by land users in upper watershed. Thus it may be prevention of the off-site impacts of soil erosion that motivates an expansion in the use of soil conservation measures. Whatever the motivation, an expanded effort is needed urgently, particularly in the tropics.

INTRODUCTION

The conservation of soil and water resources is a major challenge to humankind because these resources are under stress to produce food and fiber to meet the needs of a burgeoning population. Consequently, poor land management associated with land clearing and agricultural intensification has caused widespread land degradation. Most natural ecosystems with climax vegetation display a dynamic equilibrium between soil formation and erosion. This equilibrium is displaced when vegetation is cleared or overgrazed, and when fire and mechanical cultivation expose soil to water and/or wind erosion. Apart from agricultural intensification, construction of roads and buildings causes serious, but commonly localized, problems of soil erosion. Loss of the soil-surface layer, which contains the highest level of nutrients and organic matter, reduces soil fertility and hence vegetative growth and yields. The broad scale of human-induced land degradation due to soil loss on agricultural lands is indicated by the estimates of Oldeman et al.^[1] Globally, the total area affected by moderate to serious soil erosion is 1028 million hectares, of which 748 million hectares is because of water erosion and the rest by wind erosion. Asia and Africa together make up 673 million hectares of the total affected area. Oldeman also estimates that 186 million hectares are affected by chemical and physical degradation, which reduce vegetative cover and exacerbate soil losses by erosion.

SOIL CONSERVATION— THE EVOLVING PARADIGM

Soil conservation may be defined as the protection of soil against physical loss by erosion or against chemical deterioration. This entry emphasizes soil erosion and its control. Human efforts to combat soil erosion on steepland areas date back to the dawn of recorded history. Indigenous technologies, documented,^[2,3] include a wide range of methods that comprise terraces, minimum tillage, handmade ridges, natural vegetation strips, stone bunds, logs, etc. (Table 1). Some of these technologies, conceived over the centuries in tune with the diverse belief systems of the people, are similar to those based on modern science, which will be discussed later. Soil erosion affects not only the productivity of the individual farm, but also the long-term capacity of a society to produce food for its population. The importance of the social dimensions of soil erosion is reinforced by the off-site impacts of transported soil or sediment in the landscape in the case of water erosion and the environmental impacts on air quality and dust deposition of airborne soil particles in the case of wind erosion. These off-site impacts may affect urban population at long distances from the site of the erosion, and in some spectacular cases—such as the Dust Bowl in the United States in the 1930s—have drawn the attention of policy makers to the need for more investment in soil conservation in rural areas. Models for the most effective community and the government's involvement in soil conservation continue to evolve.

Source: ^a<http://www.wocat.net/materials/qtqalist.pdf>.^[3]

In the 20th century, governments in countries with mechanized modern agriculture, such as the United States, recognized the serious problems created by erosion and established institutions to promote and subsidize soil conservation. A land classification scheme was developed to identify high-risk erosion-prone land that was in some cases set aside as natural rangeland. On other classes of vulnerable land, agronomic practices, and/or conservation structures such as contour banks, were introduced on an individual farm basis with the help of government agents. Some developing countries introduced similar schemes. However, these efforts have not been successful in many countries. In the United States, despite massive investments in soil conservation since the 1930s, some experts believe that the rates of soil erosion have not declined.^[4] Many practitioners consider that traditional top-down soil conservation programs should be replaced by systems utilizing community-based approaches. Movements such as the landcare program in Australia^[5] and conservation districts in the United States^[6] are based on a bottom-up approach in which members of rural communities work together to conserve not only the soil and water resources but also, on the basis of a more holistic approach, the biodiversity and landscape integrity.

The limited successes of soil conservation schemes contributed to concerns about global environmental security that in the mid-1980s led to widespread acceptance of the concept of sustainability. The World Commission on Environment and Development defined sustainable development as meeting the needs of the present without compromising the ability of future generations to meet their own needs.^[7] This new thinking also recognized that technological innovation is a necessary but not a sufficient requirement for successful soil and water conservation. A new paradigm that shifted from an emphasis on soil and water conservation to the more holistic goal of sustainable land management was developed. The shift entailed a change from a technology-based approach to an approach designed to preserve and enhance the quality and productivity of global natural and environmental resources, with a view to the dynamic and constantly changing needs of all of the

earth's inhabitants.^[8] The scales of intervention ranged from the household through the community to the international level, involving treaties and conventions.

At the farm and field level, a mechanism is needed for assessing sustainable land management. The framework for evaluating sustainable land management (FESLM) was designed for this purpose.^[9] The FESLM sets the goal of a system that combines technologies, policies, and activities aimed at integrating socioeconomic principles with environmental concerns so as to simultaneously maintain or enhance production/service; reduce the level of production risk; protect the potential of the resource base; be economically viable; and socially acceptable. These objectives—productivity, security, protection, viability, and acceptability—constitute the five pillars of the FESLM.

This broad view of sustainable land management, involving social and economical as well as biophysical dimensions, requires a new community-based approach to institutional support. Farmer participation is the key to success in both developed and developing countries although the most appropriate frameworks for community, institution, and government involvement vary. In developing countries, there is an increased adoption of participatory technology development that involves farmers in the planning, collection, selection, testing, and dissemination of technologies. The landcare approach in Australia is an example of the new approach in the context of a developed country. Landcare was initiated to address the failure of the conventional government soil conservation approach to halt the disturbing rate of natural resource degradation in Australia; in 1996, there were 3000 landcare groups.^[10] The model is based on government support of these landcare groups consisting of a collection of farmers and interested citizens joined together to reverse natural resource degradation. The roles of communities and governments at different levels in underpinning the landcare movement are evolving and are critically important to the ultimate success of these soil conservation efforts. The policy interventions needed in developing countries must take account of credit, land tenure, and pricing policies that strongly influence the actions of farmers in marginal areas.^[11]

EROSION CONTROL

The control of soil erosion can be achieved using a wide range of technologies, both vegetative and mechanical (Table 2). The principles underlying these control measures have been summarized in models such as the USLE, RUSLE, WEPP^[13] and GUEST.^[14] Rainfall impact is a key factor in dispersing and detaching the surface soil, hence soil cover that protects the surface is an important factor in selecting technologies to control erosion. However, because surface runoff plays an overriding and critical role in most erosion, control measures should generally be selected to increase infiltration and thereby reduce runoff, or to slow the surface runoff rate by reducing the degree of slope or slope length. In tropical steepplands with high rainfall rates, high surface runoff rates create high stream power leading to unacceptable erosion rates higher than 100 t/ha/yr. Some soils with initially high infiltration rates have no runoff until the profile is saturated by tropical storms, then upwelling and runoff occur leading to high soil losses.^[14] For erosion control, the choice of technologies from lists such as those in Table 2 depends on the biophysical, social, and economical characteristics of the site. Use of schemes such as the FESLM discussed earlier helps ensure that the technology(ies) chosen lead to sustainable land management.

Lal^[15] presented the rationale to consider the watershed as the basic unit for sustainable land and water management. Because erosion processes of detachment, transport, and deposition operate in the landscape, effective erosion control requires an understanding of those processes, and the hydrological processes and their impact in the watershed scale. The trend toward integrated watershed management as the basis for natural resource management is consistent and adds weight to the shift toward community-based land management discussed in the previous section on soil conservation.

Control of wind erosion presents a difficult challenge, particularly in the developing world. The underlying causes are overgrazing and removal of crop residues in cultivated fields in dry areas. The first line of defense is to reduce stocking rates or retain residues in the field. However, these techniques, and long-term solutions such as the planting of windbreaks, are not within the realm of economic possibilities for poor farmers in regions such as West Africa. Nevertheless, Stirk^[16] showed that farmer-managed regeneration of woody species was a promising and effective approach to reduce wind erosion without reducing income or requiring too much investment of labor or capital. Once again, this illustrates the principle that all the dimensions of sustainable land management must be considered to achieve successful erosion control.

CONCLUSION

The prospects for better control of soil erosion have improved in years. Our knowledge of the human and biophysical factors affecting soil erosion has been improved through the use of new methods such as GIS-based multiaгент modeling; in particular, by locating and targeting erosion hotspots in the landscape, the GIS methods can greatly improve the effectiveness of soil conservation programs. Furthermore, in some developed countries, the elaboration of the concept of multifunctionality of agricultural land will foster approaches and practices that take into account important ecosystem services such as biodiversity protection, landscape integrity, carbon sequestration, and watershed protection. For the developing countries, there have been moves to devise schemes to subsidize the ecosystem services provided by land users in upper watershed. Thus it may be prevention of the off-site impacts of soil erosion that motivates an expansion in the use of soil conservation measures. Whatever the motivation, an expanded effort is needed urgently, particularly in the tropics.

Erosion: Water Quality

Andreas Klik

Department of Water, Atmosphere and Environment, University of Natural Resources and Applied Life Sciences, Vienna, Austria

Abstract

Soil and water quality problems caused by agricultural production practices are receiving increased attention and are partly perceived by society as important environmental problems. Agricultural land use has a great impact on soil erosion and sediment deposition as well as on water quality. Sediment input is the most polluting source of aquatic ecosystems worldwide. Severe soil degradation from soil erosion by wind and water can destroy the productive capacity of the soil. Sediments as well as nutrients, pesticides, salts, other trace elements, pathogens, and toxic substances (which are either attached to sediments or dissolved in surface runoff) lead to contamination of surface and groundwater bodies and diminish water quality.

INTRODUCTION

The adjustments and modernization of agriculture has led to considerable changes of the agricultural landscape. To increase economic efficiency, changes were made mainly in land use, crop production, crop rotation, fertilizer management, and pest control. These human impacts affected the stability of agricultural ecosystems. Soil erosion by wind and water increased in many parts of the world, resulting in negative changes of soil and water resources.

EFFECTS OF SEDIMENTS

Within a watershed, various soil erosion processes including detachment, transport, and deposition occur. Their magnitude mainly depends on slope, soil, and topographic and land use conditions and can greatly vary within an area. Although high erosion rates can be reached in a watershed, not all sediments may reach surface water bodies because of deposition nearby.

According to estimates, on a global scale sediments carried into the oceans increased from 9 billion tons per year before introduction of intensive agriculture, grazing, and other activities to between 23 and 45 billion tons thereafter.^[1] Of the total 0.9 billion tons of sediments carried by rivers from the continental United States, about 60% is estimated to come from agricultural lands.^[2] In the Chinese Loess Plateau, total soil loss is estimated to be about 2200 million tons annually. Three-quarters of the total soil loss is transported to the lower reaches of the Yellow river.^[3] Therefore, average sediment concentration of Yellow river is 38 kg/m, 20 times higher than that of the Nile River in Egypt and 38 times higher than that of the Mississippi

River. During periods of floods, silt content in the Yellow River can rise to more than 650 kg/m.

Different erosion processes produce different sediment qualities. Sheet or inter-rill erosion usually produces fine-textured sediment from topsoil layers. These layers contain the bulk of agriculturally applied chemicals that attach to and move with the eroded soil. Channel erosion produces sediment from all soil layers incised by this erosion process. Stream banks erode into previously deposited alluvial sediments that normally do not contain significant amounts of agrochemicals.

High concentration of suspended sediments in streams diminishes their recreational uses because pathogens and toxic substances commonly associated with suspended sediments are threats to public health. High sediment concentrations reduce water clarity and the esthetic appeal of streams. Suspended sediment is also harmful to stream biota; it inhibits respiration, diminishes the transmission of light needed for plant photosynthesis, and promotes infections. Sediment depositions can lead to suffocation of benthic organisms.

EFFECTS OF NUTRIENTS

For growth of plants and animals, macronutrients, such as nitrogen (N), phosphorus (P), potassium, sodium, sulfur (S), magnesium (Mg), and calcium (Ca), and micronutrients, such as boron, molybdenum, chlorine, iron (Fe), manganese, and others, are essential. When input in surface water bodies, N and P especially can increase their biological productivity. Although N and carbon (C) are essential to the growth of aquatic biota, the focus of attention was on P inputs, because of the difficulty in controlling the exchange of N and C between the atmosphere and water,

Table 1 Dissolved load from different continents to the world's oceans.

Continent	Dissolved load (106 Mg/yr)
Africa	201
Asia	1592
Europe	425
North and Central Europe	758
Oceania/Pacific Islands	293
South America	603
Total	3872

Source: From Walling.^[4]

and fixation of atmospheric N by some blue-green algae. Thus, P is often the limiting element and its control is of prime importance in reducing the accelerated eutrophication of fresh waters. Walling^[4] calculated that globally the transport of a dissolved P (DP) load from different continents to the oceans is about 4 billion tons per year (Table 1).^[5]

In undisturbed rivers, total P concentrations are generally lower than 25 µg P/L. Concentrations higher than 50 µg P/L result from human activities. Investigations show that considerably more than half of all European river stations exceed that level. In Europe, the highest levels are found in a band stretching from the northwest across the middle part of the continent, reflecting the intensity of agriculture and livestock production in these regions.^[6] From 1980 to 1989, average P concentrations in U.S. freshwater ecosystems were 0.1 mg/L or greater. Concentrations greater than 0.5 mg/L were especially common in the central and south-central regions, where extensive agricultural use of P and highly erodible soils combines to create large non-point source loadings.^[7] Nationwide measurements since 1991 showed that annual amounts of total P and total N measured in agricultural streams were equivalent to less than 20% of P and less than 50% of the N that was applied to the land.^[8] In more than one-half of sampled streams and in three-fourths of agricultural and urban streams, average annual concentrations of total P exceeded the U.S. Environmental Protection Agency desired goal for prevention of nuisance plant growth. The highest total N and total P concentrations were found in small streams draining watersheds with large proportions of agricultural or urban land.

Nitrogen

Most of the N in the soil is stored in soil organic matter. This N is transformed through mineralization into ammonium ions (NH₄) and released into the soil. Ammonium adsorbs to clay minerals and organic matter and can be transported to surface water attached to sediment or suspended matter. Nitrification transforms ammonium ions to

nitrite (NO₂) and nitrate (NO₃). Nitrate is totally soluble and moves freely in solution.

The dominant factors in the loss of N in runoff are the amount and timing of rainfall and soil properties. Much of the N that enters the rivers is associated with eroded sediments and eroding soil organic matter or it is dissolved in surface runoff. Runoff during rainfall or snowmelt may have a high concentration of organic N attached to sediments but is typically low in NO₃ concentration. Most rains have a significant wetting period before runoff starts. Soluble fertilizer is carried down into the soil during these first few minutes, so little is lost in the runoff. Exceptional losses can occur if intense rain strikes very suddenly or if rain cannot infiltrate because of frozen or impermeable soil, or if water exfiltrates at the foot of the hillslope because of near-surface hydraulic gradient.^[9]

High NO₃ levels in water are a critical concern for human beings because ingestion of such water has the potential to reduce the oxygen-carrying capacity of the blood. When NO₃ is reduced to NO₂⁻, it oxidizes the Fe of the hemoglobin in the blood and methemoglobin is formed, which cannot carry oxygen.^[10] Infants are more endangered to suffer these ill effects than are adults.

Phosphorus

Soil P exists in inorganic and organic forms. In most agricultural soils, 50–75% of P is inorganic, although this fraction can vary from 10% to 90%. Inorganic P forms are dominated by hydrous sesquioxides and amorphous and crystalline Al and Fe compounds in acidic and non-calcareous soils and by Ca compounds in alkaline and calcareous soils. Organic forms include relatively labile phospholipids, nucleic acids, inositols, and fulvic acids, while more resistant forms comprise humic acids. The liability of these forms of P is based on the extent to which extractants of increasing acidity or alkalinity, which are applied sequentially, can dissolve soil P.^[11]

During erosion processes, P can be transported by surface runoff in DP and particulate P (PP) forms. PP includes P attached to eroded soil particles and absorbed by organic matter. PP constitutes the major fraction of P transported from cultivated land with values between 60% and 90%.^[12,13] Runoff from grass or forest land carries little sediment and is therefore generally dominated by DP. While DP is immediately available for biological uptake, PP can provide a long-term source of P for aquatic biota.^[14] Not all P transported by sediments is bioavailable.^[15] Sediment transported P that is not presently bioavailable may become bioavailable,^[16] with the release of P depending on the nature of the sediment and surrounding environment. Under regular pH and aerobic conditions in aquatic systems, P is present as secondary or tertiary phosphate and combines with Fe as a heavily soluble substance that is deposited in the sediment. Under anaerobic conditions (i.e., oxygen shortage), Fe has a higher affinity to S and

combines with it under production of Fe sulfide; P is then released and again available as nutrient for aquatic biota.^[17]

As P is usually the limiting factor in surface water bodies, each increase of P concentration leads to increased growth of undesirable algae and aquatic weeds and oxygen shortages, and subsequently to problems with fisheries and water used for recreation, industry, and drinking. Massive surface blooms of cyanobacteria (blue-green algae) lead to

fish kills, make drinking water unpalatable, and contribute to the formation of trihalomethane during water chlorination.^[18] The consumption of algal blooms or of the water-soluble neurotoxins and hepatotoxins released when the algae die can kill livestock and may pose a serious health hazard to humans.^[19]

Most of the annual nutrient losses measured in surface runoff are associated with sediment losses. Data in [Table 2](#)

Table 2 N and P losses associated with surface runoff (R) and soil loss (S) as well as total losses (T).

show that losses of soluble N and P in runoff water are usually much less than the losses of these nutrients transported attached to sediments. Soil erosion protection measures like contouring or no-till management are able to diminish nutrient losses by reducing soil loss.

EFFECTS OF PESTICIDES

Pesticides are used to protect food and fiber from damage by weeds, insects, diseases, nematodes, and rodents. When used properly, modern pesticides can perform their

functions without causing significant hazards to humans or to the environment. The most serious long-term effects of pesticides on humans are cancer, genetic defects, and birth defects. Effects on non-target organisms may lead to a decreasing biodiversity.

The application of pesticides in the European Community fell between 1985 and 1995, but this does not necessarily indicate a decrease in environmental impact because the range of pesticides in use has changed.^[6] In United States, the potential for pesticide runoff loss is greatest for watersheds in the Midwest and the Mississippi Embayment.^[27]

The persistence of a pesticide in the environment and three physical properties of pesticides—soil sorption propensity, solubility, and vapor pressure—determine the tendency of pesticides to move from the application site.^[38,39]

Persistence is a pesticide’s resistance to decomposition through chemical, photochemical, and microbial action. It is expressed in terms of half-life (in days). It varies from a few hours to months depending on the pesticide and the local environment. Pesticides that persist are more likely to move off-site than less persistent ones. Most pesticides decompose into less toxic chemical forms, but sometimes the metabolites retain pestical properties.

Sorption is the binding of the chemical to the soil. Some pesticides are preferentially transported and adsorbed to entrained sediments. Wauchope^[40] found that those pesticides with solubility below 2 mg/L are transported primarily by sediment. As soil organic matter is mainly responsible for adsorption of non-ionic organic compounds, sorption is commonly evaluated by using a sorption-partitioning coefficient (Koc, expressed in ml/g) based on the organic carbon content of the soil.

Water solubility (expressed in mg/L) determines how easily it goes into solution with water. Simply being water soluble does not mean that a pesticide will leach into groundwater or runoff into surface water. However, solubility means that if a soluble pesticide somehow gets into water, it will probably stay there and go where the water flows. Although the relation between soil sorptivity and water solubility is complex, it is generally true that given a particular soil adsorption level, the greater the solubility, the more potential there is for losses from the field when it rains.

Vapor pressure (expressed in mmHg) is the measure of a pesticide’s tendency to evaporate. Wind speed, air temperature, soil temperature, humidity, and equipment determine the amount of losses to the atmosphere.

Soil, pesticide, and rainfall characteristics influence the timing and amount of pesticide loss^[41,42] and the dominant transporting agent of that pesticide. Pesticide persistence and sorption properties influence the time they stay near

their application site and whether they will be adsorbed to sediment or remain in solution phase. Pesticide persistence and sorption determine, in part, the probability of loss by runoff, and in what form the loss will occur (in solution/runoff water or adsorbed to sediment). Percentage of pesticide in runoff and on sediment will depend not only on sorption properties but also on the time elapsed since application^[43] and on the processes controlling runoff and sediment production during rainfall.^[44,45] Those pesticides that are strongly sorbed to soil clays and organic matter may be subject to removal by surface runoff or wind. Other pesticides that are weakly sorbed and have high water solubility may be lost in the dissolved state.

In Table 3, the results from field experiments with natural and simulated rainfall about losses of different pesticides associated with runoff are summarized. In many studies, the bulk of measured pesticide losses occurred in a single storm soon after pesticide application. Therefore, pesticide runoff losses from simulated rainfall may be higher than that from natural rainfall studies. Examples of reports of pesticides in surface waters are shown in Table 4.

CONCLUSION

Further, it will be difficult to prevent contamination of water bodies by sediments, nutrients, pesticides, salts, and other pollutants if soil degradation is not controlled. Worldwide, there already exist various effective soil erosion control practices and measures. They are able to reduce soil erosion by wind and/or water and therefore to prevent negative on-site and off-site impacts. Additionally, predictive tools are available to identify problem areas and to perform and evaluate environmental sound watershed management to achieve sustainable land and soil use. We have to keep in mind that soil and water quality are inherently linked; conserving or enhancing soil quality is a fundamental step to improve the quality of our surface and groundwater bodies. Improvement of the quality of both resources (soil and water) will be essential for future generations.

Erosivity and Erodibility

Peter I.A. Kinnell

*School of Resource, Environmental and Heritage Sciences, University of Canberra,
Holt, Australian Capital Territory, Australia*

Abstract

In water erosion, erosivity and erodibility are the terms used to identify rain-associated factors driving erosion and the susceptibility of the soil to erosion. Their application in modeling erosion in empirical and process-based models will be described and discussed.

THE UNIVERSAL SOIL LOSS EQUATION (USLE)

Historically, the terms “erosivity” and “erodibility” were originally associated with the R and K factors in the following USLE:

$$A = RKLSCP \quad (1)$$

where A is the annual average soil loss per unit area, R is the rainfall-runoff (erosivity) factor, K is the soil (erodibility) factor, L is the slope length factor, S is the slope gradient factor, C is the crop and crop management factor, and P is the support practice factor.^[1,2] Fundamental to the USLE is the concept of the unit plot—a bare fallow plot having a slope length of 72.6 ft (22.1 m), a slope gradient of 9%, and cultivation up and down the slope. For the unit plots, the following expressions are used:

$$C = L = S = P = 1.0$$

and

$$A = RK \quad (2)$$

In the USLE, R is defined as the average annual value of the product of the total storm kinetic energy and the maximum 30-minute intensity for rainfall events producing at least 0.5 in. (12.5 mm) of rain or at least 0.25 in. (6.35 mm) of rain in 15 minutes. In the Revised USLE (RUSLE),^[3] all rainfall events were considered in calculating R in the western part of the United States. Customary U.S. units for R are $10^2 \text{ ft T}_f \text{ in./A/hr/yr}$ (hundreds of foot-Tonf-inch per Acre-hour-year) and K are $\text{TA hr} \times 10^{-2} / \text{ft T}_f \text{ in.}$ (Ton-Acre-hour per hundreds of foot-Tonf-inch). Customary metric units are MJ mm/ha/hr/yr (megajoule-millimeter per hectare-hour-year) and t hr/MJ/mm (metric ton-hour per megajoule-millimeter).^[3]

K is essentially the regression coefficient for the direct relationship between R and A under unit plot conditions. Experimental plot data were used originally to determine the values of K. Subsequently, equations have been

developed to predict K from soil properties in various geographic locations.^[2–4]

The USLE model works reasonably well in some locations (Fig. 1A) but does not in others (Fig. 1B). The USLE is less effective when the soil has a high capacity to accept rainfall.^[5] In the latter situation, there is a tendency for the USLE to overestimate low annual soil losses. Including runoff in the storm erosivity factor by multiplying the EI_{30} index by the runoff coefficient (Q_R , runoff amount divided by rainfall amount) provides a model known as the USLE-M^[5] which, as can be seen by comparing Fig. 2 with Fig. 1, is better able to deal with the effect of differences in soil infiltration characteristics. It should be noted that, as indicated by the different regression coefficients shown in Figs. 1B and 2, any change in the event erosivity index from the product of event energy and the maximum 30-minute intensity means that the USLE K factor values cannot be used.

MORE PROCESS-BASED APPROACHES

The USLE is designed to predict erosion from sheet- and rill-eroded areas. Modern understanding of erosion processes recognizes that the energy required for soil detachment associated with rill erosion comes from flow energy, while detachment in sheet and inter-rill erosion is dominated by energy derived from raindrop impact. The USLE does not take these different energy sources into account. So more process-based models have been developed to overcome this limitation. Rill and inter-rill erosion equations have been developed within the U.S. Department of Agriculture's Water Erosion Prediction Project (WEPP).^[6] In the rill equation,

$$D_r = K_r(\tau - \tau_0)(1 - q_s T_{cf}^{-1}) \quad (3)$$

D_r is rill detachment, K_r is the rill erodibility, τ is the flow shear stress, τ_0 is the critical shear stress, q_s is the sediment load, and T_{cf} is the sediment load when the transport

capacity is reached. τ_0 is a soil-dependent parameter. However, it is not considered to be an erodibility factor. In the basic inter-rill equation,

$$D_i = K_i I_e I_x S_f \quad (4)$$

D_i is inter-rill detachment, K_i is the inter-rill erodibility, I_e is the effective rainfall rate during the period of excess rainfall, I_x is the excess rainfall rate, and S_f is a function of

inter-rill slope. Base values for K_r and K_i have been determined from experiments undertaken on a number of soils in the United States.^[6] In practice, the base values for K_r and K_i are adjusted to account for various effects including roots, sealing, and crusting to predict soil loss. The surface conditions of freshly tilled soils impacted by raindrops change over time, and this causes the susceptibility of the soil to erosion to change with time. The base values for K_i were determined from data usually collected after rain at 62 mm/hr had been applied to short (250 mm long slopes) inclined slopes for 30 minute or more to ensure reasonably stable surface conditions.

Although inter-rill erosion is dominated by detachment caused by raindrop impact, there are a number of detachment and transport processes that can occur during a rainfall event. At the onset of rain on a dry surface, material detached by raindrop impact is splashed down slope. This is shown as raindrop detachment–splash transport (RD–ST) in Fig. 3. The RD–ST system controls what is commonly known as splash erosion. Before detachment can occur, a raindrop must possess sufficient energy to detach soil material from the cohesive forces that hold that material within the surface layer. This critical energy is indicated by e_c . e_c tends to increase during rain as, e.g., a surface crust develops, and this contributes to a decrease in soil erodibility associated with splash erosion. As runoff develops, raindrops penetrating the flow lift soil material into the flow,

and this material moves downstream in the flow. This detachment–transport system is called the raindrop detachment–raindrop induced flow transport (RD–RIFT) system, and it requires both raindrop impact and flow to operate. On short slopes, if the slope gradient is sufficiently high, flow can entrain loose material on the surface without the aid of raindrop impact. This produces a raindrop detachment–flow transport (RD–FT) system. The flow detachment–flow transport (FD–FT) system is normally associated with rills but can also occur on short high-gradient slopes. In principle, each detachment–transport system can be represented by an equation that has an erosivity term and associated erodibility term. As all the detachment–transport systems may operate to various degrees in any given area depending on the prevailing conditions, inter-rill erodibilities are less predictable than rill erodibilities.

In the USLE, soil erodibility (K) was kept constant during the calculation of the annual soil loss, while interaction between short-term variations in erosivity and crop factors was considered in determining C values. In RUSLE, K can be considered to vary during the year. At the process model level, changes in the soil surface conditions associated with, e.g., the development of soil crusts have been noted already as having an effect on erodibility. However, erosion is limited by either detachment or transport processes. Crusts influence detachment, but transport-limiting conditions need to be considered in modeling erosion. In the WEPP rill model,^[6] this is achieved by the term $1 - q_s T_{CF}^{-1}$. The RD–ST and RD–RIFT are inherently transport-limited systems because material detached by drop impact tends to fall back to the soil surface and is remobilized by numerous drop impacts before being discharged from the eroding area. The material on the surface, near the end of the eroding area, contributes directly to the material being discharged and also protects the underlying surface to some degree. This influences erodibility.^[8] For the RD–RIFT systems, erodibility is given by the following equation:

$$K_i = H_{PD} K_{iPD} + (1 - H_{PD}) K_{iM} \quad (5)$$

where H_{PD} is the degree of protection provided by the previously detached material, K_{iPD} is the erodibility when the previously detached material fully protects the underlying surface, and K_{iM} is the erodibility of the soil surface when there is no previously detached material upon it. However, because H_{PD} and the composition of the previously detached material vary with flow conditions and particle characteristics, H_{PD} and K_{iPD} vary in time and space. Relatively complex mathematical models that consider particle characteristics^[9] have been developed with the aim of dealing with this variation.

SIMPLE CONCEPT FOR COMPLEX SYSTEMS

Originally, the concept of erosivity and erodibility as considered in the USLE was quite simple because the model

was designed to predict long-term average annual soil loss based on experimental data. Equations developed to predict K and C enabled the model to be applied to areas and situations not covered in the original experiments. However, the USLE and the RUSLE do not capture the effects of some of the fundamental erosion processes well in some cases. To overcome this deficiency, more process-based models have been developed. However, because the susceptibility of the soil to erosion can vary in space and time as a result of an interaction between the soil surface and the detachment and transport mechanisms, erodibility can vary in time and space in a complex manner. Complex process-based mathematical models may be needed to account for this variation, but less complex models may produce sufficiently accurate results to make reasonable decisions on land management options. Runoff is an important factor in rainfall erosion. Models that include it as part of the erosivity factor have the potential to account for erosion better than those that do not.

Ethics

John Ronald Engel

Center for Humans and Nature, Beverly Shores, Indiana, U.S.A.

Abstract

This entry presents the following six arguments as to how soil ethics can contribute to the making of a new global covenant committed to universal principles of sustainability, justice, and peace: 1) Land care is exemplary of the necessity of addressing the environmental and social issues of our planet together; 2) soil integrity is the sine qua non of ecological and biospheric integrity; 3) soil “stewardship” is an essential component of the covenants we make between the generations; 4) the need for precaution in the ways we treat soil, given the limits of our scientific and practical understanding of how to preserve and restore it, demonstrates the importance of the precautionary principle; 5) soil conservation requires a “common but differentiated” approach to our cultural as well as economic and technological capacities for land care; and 6) the evolutionary and spiritual solidarity we experience with the earth through soil is a strong naturalistic foundation for our ultimate commitment to sustaining the life of the planet.

I am the Living Earth, I am the softened tissue of rocks, baked by the sun, split by ice, carried by water, and winnowed by the wind. I am interwoven by myriads of tiny plants and animals that pulse and breathe. I am the invisible universe of sparkling molecules in the infinity of living soils that bless the mantle of the globe.

—*Len Webb*

That land is a community is the basic concept of ecology, but that land is to be loved and respected is an extension of ethics.

—*Aldo Leopold*

MAKING THE GLOBAL COVENANT

Calls for a New Global Covenant

Over the course of the last several decades, calls for a new earth covenant have come from all quarters of the globe.^[1] Sometimes the call is for a “new global compact,” a term used by United Nations Director Generals Javier Perez de Cuellar and Kofi Annan. But more prophetically and accurately in the words of Liberation Theologian Leonardo Boff and Political Philosopher David Held, it is a call for “a new covenant with Earth.” These calls presume that we are citizens of the world as well as of nations, that we live in an interdependent planetary community, and that if we are to overcome the tragedy of the global commons, we must reach agreement on the fundamental moral principles of global governance.

Covenants are open, unconditional commitments to be faithful to others regarding our most fundamental

values and behaviors, and they have historically served as the spiritual and moral authority for national constitutions and international treaties. “Covenant” and “compact” are often used interchangeably to describe public agreements of unlimited duration that require mutual consent to be abrogated, but covenant typically places primary emphasis on the moral dimension, while compact on the legal. Both need to be distinguished from contracts, which are limited agreements for the sake of a utility of direct benefit to the consenting parties and which are dissolved once that utility is obtained. Calls for a new global covenant or compact recognize that to address issues as daunting as climate change we need not only new and better contracts but a transformation in our personal and collective loyalties.

The Earth Charter and the Proposed Soil Charter

Officially launched in The Hague in 2000, the Earth Charter, which may be accessed at www.earthcharter.org, is the most complete public statement we have of the moral and spiritual vision of a new earth covenant. As a people’s treaty circulated throughout the world, with endorsements by hundreds of nongovernmental organizations, municipalities, national governments, and international agencies, it is the most legitimate as well. The Earth Charter may be viewed as a landmark in the series of repeated attempts since the drafting of the United Nations Charter and the Universal Declaration of Human Rights, including the long line of soft law declarations on environment and development running from the 1972 Stockholm Declaration on the Human Environment to the

2000 Millennium Development Goals, to rewrite the global compact along more comprehensive covenantal lines. Like its precursor, *Caring for the Earth*, the Earth Charter affirms “respect and care for the community of life”—a time-honored covenantal principle—as the overarching principle of moral obligation.^[2]

One of the most significant contributions the Earth Charter can make at this juncture in world history is to serve as a framework and catalyst for continuing the dialogue on global ethics and moving the international covenant-making process forward.

Soil health is one of the most critical, if neglected, components in the well-being of the biosphere and the human civilizations that depend on it. Our readiness to assume responsibility for it must be considered an essential part of the movement to create a new global covenant committed to universal principles of sustainability, justice, and peace.

Reading the Earth Charter with soil and soil responsibilities in mind, we can see that it is not a complete or fully adequate document. “Soil” is mentioned only three times and those in passing. Nonetheless, the Charter is an invaluable resource for understanding the basic moral approach we need to take soil and the moral guidelines we need to follow for promoting better land care throughout the world, while an explicit elaboration of soil ethics can substantially improve the Charter’s conceptual foundations and practical effectiveness. On this basis, we may greet the prospects of a dialogue between the Earth Charter and a revised World Soil Charter and World Soils Policy, or a new Global Charter for Land Care and a “new, binding, international instrument concerning the protection and sustainable use of soils,” as suggested in the Program of Action that emerged from the 2007 Selfoss Forum on Soils, Society, and Global Change, as a positive step toward advancing both the conservation of soil and the earth covenant.^[3]

THE CONTRIBUTIONS OF SOIL ETHICS TO THE NEW GLOBAL COVENANT

Eco-Justice

The most significant development that may be traced through the long line of international declarations that paved the way to the Earth Charter is the recognition, beginning at Stockholm, that the most urgent environmental issues of the world are inseparable from the most urgent issues of social justice. Growing awareness of these relationships fueled the discussion of “sustainable development” in the 1980s and “just and sustainable communities” in the 1990s and has subsequently expanded to include security and peace. The Earth Charter expresses this evolution in global ethics in its explicit adoption of what has come to be called an “eco-justice”

ethic, an integrative moral approach in which ecological and social (including economic, political, and cultural) well-being are considered as both dependent and independent variables. The 71 principles of the Earth Charter spell out our obligations for “Ecological Integrity,” “Social and Economic Justice,” and “Democracy, Non-violence, and Peace,” not only by attending to the specific obligations we have for each of these basic moral concerns but also by spelling out the relationships between them. Principle 7, e.g., expresses the imperative of integrating a wide range of interdependent ecological and social values: “Adopt patterns of production, consumption, and reproduction that safeguard earth’s regenerative capacities, human rights, and community well-being.”

In past years, out of a laudable zeal to bring attention to the devastating degradation of soils across the world, advocates of soil conservation often isolated the values of land care from other great questions of global ethics such as poverty, human rights, and military conflict. There were tendencies to interpret soil as primarily a resource commodity and to restrict the moral concern for soil to its role in agriculture, thus neglecting the many different and critical roles soils play in the evolution and ecology of the planet.

The 2007 Selfoss Forum on Soils, Society, and Global Change took major strides toward breaking this single-minded vision. The presentations forthrightly addressed the intimate connections of soil health to other matters of global concern such as climate change, poverty, biodiversity loss, and unrestrained economic and population growth. It made clear why we cannot hope for significant change in soil conservation values and practices without addressing these other issues and putting into practice principles of social and economic justice, human rights, democratic participation, nonviolence, and international law, nor can we hope to make significant headway on these global social issues without paying more attention to the functions soil performs in sustaining the ecosphere and human civilization. The Forum thus not only lifted up the crucial importance of soil for the future of humankind and the planet but also showed how soil demonstrates the validity of the strong eco-justice approach of the emerging earth covenant.

Ecological Integrity

A distinguishing feature of the Earth Charter is the prominent place it gives to ecological integrity as an ethical as well as a scientific principle. The second of the four main sections of the Charter is entitled “Ecological Integrity.” Principle 5 states “Protect and restore the integrity of earth’s ecological systems, with special concern for biological diversity and the natural processes that sustain life.”

Brendan Mackey, professor at Australian National University and the member of the Earth Charter drafting

committee most responsible for its emphasis on ecological integrity, writes that “ecological integrity can be understood in terms of the capacity of earth’s ecosystems to continue flourishing so that the environmental services are maintained upon which the well-being of humans and all life depend.”^[4] A major contribution that soil ethics can make to the earth covenant is to emphasize the fact that soil integrity is both a critical component of ecological integrity and its *sine qua non*—without which there will not be ecological integrity.

An influential figure in the field of soil conservation and environmental ethics who can help make that argument is Aldo Leopold (1887–1948), an American forester and wildlife, ecologist whose book, *A Sand County Almanac*, recounts his experiences restoring a tract of land on the Wisconsin River and climaxes in a proposal for a “land ethic” that makes ecological integrity a first principle of environmental ethics.

The primary motivation of Leopold’s career was what he called “the oldest task in human history to live on a piece of land without spoiling it.”^[5] He came to that understanding as a result of his firsthand experiences in soil erosion and degradation, first in the rangelands in the American southwest and then in the agricultural areas of the midwest. In 1921, he wrote:

With enough time and money, a neglected farm can be put back on its feet—if the soil is still there. With enough patience and scientific knowledge, an overgrazed range can be restored—if the soil is still there. By expensive replanting and a generation or two of waiting, a ruined forest can again be made productive—if the soil is still there. With infinitely expensive works, a ruined watershed may again fill our ditches or turn our mills—if the soil is still there. But if the soil is gone, the loss is absolute and irrevocable. Three years later he wrote: “Soil is the fundamental resource, and its loss the most serious of all losses.”^[6]

Leopold used “land” to describe soil, water, plants, animals, and people collectively, and he often spoke of land as a “community.” He preferred land over terms such as ecosystem because it communicated to the ordinary citizen our primary dependence on fertile soil, and his choice of community was influenced by the new field of ecology often defined as the “science of communities.” But Leopold was also well versed in the writings of the Hebrew prophets. His ideas of “land community” and land ethic may be interpreted as contemporary science-based translations of their understanding of an aboriginal covenant between God, people, and the earth. Leopold’s proposal for a land ethic may be set forth in the form of a syllogism.^[7]

1. “All ethics rest upon a single premise: that the individual is a member of a community of interdependent

parts. [It is] a limitation on freedom of action in the struggle for existence—[a way of evolving] modes of cooperation.”

2. We are members of the land community.
3. Therefore, we need to exercise the same constraints on our relations to the other members of the land community—soils, waters, plants, and animals—as we do in our relations to people.
4. Thus, the land ethic, “A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise.”

From which we may extrapolate, “A thing is right when it tends to preserve the integrity, stability, and beauty of the soil community. It is wrong when it tends otherwise.”

By “stability” Leopold meant the capacity of the land to cycle nutrients efficiently and continuously because its biotic pyramid was intact and its food circuits were open; by “integrity” he meant that the land possessed all the parts needed to maintain its stability and their successful coordination through competition/cooperation; by “beauty” he meant the “pleasing appearance to the eye, ear, and soul” of land that possesses stability and integrity.^[8] Since the mid-20th century, new scientific notions of nature as dynamic, ever changing, even chaotic, and species and individual interactions as selfish, rather than symbiotic, have challenged earlier ecological notions of nature as composed of “integrated communities” in dynamic equilibrium, with a diverse array of species in positive interactions with one another. In light of these developments, environmental ethicists such as Baird Callicott have sought to dynamize the concept of land ethic and incorporate the crucial norms of scale in evaluating anthropogenic changes in nature.^[9] Regardless, it is unlikely that ecological integrity as such defined as “the capacity of Earth’s ecosystems to continue flourishing so that the environmental services are maintained upon which the well-being of humans and all life depend” and its crucial component, soil integrity, will ever be dislodged as the primary focus of our covenantal responsibilities to the earth.^[4]

Stewardship

Global ethics must also address the covenantal dimensions of the earth community’s passage through time, and the responsibilities we bear, as individuals and societies, for passing on a healthy biosphere, including the responsibilities we bear to past, present, and future generations of humans for the sustainable use and just distribution of the resources of nature, all of which may be summed up in the ethical imperative to serve the common good.

To assume an inclusive, long-term responsibility for the good of nature and the resources humans make of nature are often identified with the idea of “stewardship.”

It is surprising that the term stewardship does not appear in the Earth Charter. Two reasons are offered for this omission. One is that no word or its equivalent could be found in some important world cultures—Russia is an example. A second is that for indigenous people the word implies a separation from nature or a paternalistic relationship, evidence, unfortunately, for the ways in which the term has taken on meanings alien to its origin. Nonetheless the principle of stewardship is included in the Charter's Preamble: "The protection of Earth's vitality, diversity, and beauty is a sacred trust" and in Principle 4: "Secure Earth's bounty and beauty for present and future generations."

Stewardship was a concept with great motivational power at the beginning of the conservation movement in the early 20th century, and it has reemerged in the ethics of "sustainable development." But its origin lies in the common property arrangements of hunter-gatherer and premodern agrarian and nomadic societies. In these societies, individual family units agreed to share land as a common property arrangement that gave each family the right of use but not ownership.^[10] This was the social context in which the biblical understanding of stewardship arose—evident, e.g., in the story of Joseph who was entrusted with the position of guardian (namely, custodian, manager, overseer, caretaker, and trustee) of the land of Egypt and who by careful oversight and foresight so conserved the produce of the land that famine was avoided and the common good secured. Patrick Dobel writes, "The stewardship imperative assumes that the moral and ecological constraints are respected, and it adds the obligation to distribute the benefits justly. The steward must 'give them their portion of the food at the proper time.'"^[11]

The "stewardship ethic" therefore has three elements: 1) long-term responsible care for the common good of nature; 2) sustainable ecological and economic use of these goods; and 3) just sharing of these goods—and these responsibilities—among the population at large.

It is difficult to imagine a more powerful example of what stewardship means in this original moral sense than stewardship of soil. It is the common property of the human and natural community, we must use it sustainably, and its care and benefits should be shared by all members of the human community.

Prevailing land use practices substitute short-term gains for wise stewardship. The addition of synthetic fertilizers may, for a time, produce yields equal to or even better than soils whose structure, moisture retention, and nutrient levels have been enriched by crop rotation and manure. Monopoly of land ownership and control can increase efficiency and help maximize soil productivity in the short run. But long-term stewardship requires soils whose inherent fertility has been retained by sound land use practices, equitable land tenure, and fair resource distribution.

In 1938, Walter Loudermilk, a close colleague of Aldo Leopold, published the first extensive documentation on the consequences of soil exhaustion in the fall of civilizations. Soon afterward, he composed what Moses might have given as the Eleventh Commandment, had he foreseen such consequences (*italics added*):

Thou shalt inherit the Holy Earth as a *faithful steward*, conserving its resources and productivity from generation to generation. Thou shalt safeguard thy fields from soil erosion, thy living waters from drying up, thy forests from desolation, and protect thy hills from overgrazing by thy herds, that thy descendants may have abundance forever. If any shall fail in this stewardship of the land thy fruitful fields shall become sterile stony ground and wasting gullies, and thy descendants shall decrease and live in poverty or perish from off the face of the earth.^[12]

The Precautionary Principle

Scientific uncertainty has frequently been used as a reason to avoid taking action to protect the environment. The precautionary principle recognizes that lack of certainty regarding the threat of environmental harm is to be expected and that this should not be an excuse for not taking action, rather it is only a reason for more positive moral approaches to the environment such as preserving ecological integrity and stewardship. The Earth Charter states the precautionary principle in those terms:

6. Prevent harm as the best method of environmental protection and, when knowledge is limited, apply a precautionary approach.

- a. Take action to avoid the possibility of serious or irreversible environmental harm even when scientific knowledge is incomplete or inconclusive.
- b. Place the burden of proof on those who argue that a proposed activity will not cause significant harm and make the responsible parties liable for environmental harm.
- c. Ensure that decision making addresses the cumulative, long-term, indirect, long-distance, and global consequences of human activities.
- d. Prevent pollution of any part of the environment and allow no buildup of radioactive, toxic, or other hazardous substances.
- e. Avoid military activities damaging to the environment.

At its core, the precautionary principle is an acknowledgment of the limits of our knowledge of the natural world and an admonition to be wary of all forms of technological and economic boosterism that promise

quick fixes to environmental problems. Accepting our finitude and ignorance requires a moral stance of humility and prudence, one that must be explicitly woven into the covenant we make with one another and the earth. The 2007 revised International Union for Conservation of Nature “Guidelines for Applying the Precautionary Principle to Biodiversity Conservation and Natural Resource Management” make this point clear: “Implementing the Precautionary principle entails ... humility and restraint, acknowledging human fallibility in the quest for certainty, the limits of science, and the tendency to over-reach in the quest for human security and well-being.”^[13]

Since our knowledge of soil and our understanding of how effectively to conserve and restore it under contemporary ecological and social conditions are limited, the precautionary principle must be an important part of soil ethics. Soil science and conservation both confirm and benefit from the Earth Charter’s strong endorsement of the precautionary principle, and the covenantal virtues of humility, restraint, and prudence that inform it.

Common but Differentiated Responsibilities

One indication that the nations of the world are groping toward a covenantal—and therefore federalist—understanding of global governance is the fact that the principle of “common but differentiated responsibilities” has become an increasingly prominent component of international law.^[14] Although the Earth Charter does not explicitly reference the principle of “common but differentiated responsibilities,” it does affirm a federal model of “partnership” for global governance in its declaration: “We are at once citizens of different nations and of one world in which the local and global are linked” and its admonition that with “increased freedom, knowledge, and power comes increased responsibility to promote the common good.”

Informed by formal principles of global equity and justice, international agreements such as the 1992 United Nations Framework Convention on Climate Change have focused on the implications of the principle for economic, political, and technological differences, and these are undoubtedly important considerations for understanding the respective obligations of different nations to address global soil issues, but the principle can also illumine another aspect of our understanding of the interdependence of soil, society, and global change. It can help us to grasp the importance of the diverse ways in which cultural attitudes and belief systems impact our relationships to the land. How we understand and discharge our responsibilities for soil are rooted in the distinct biogeocultural narratives of our several societies. As indicated in the Program for Action of this forum “[e]xperiences of soil stewardship and restoration efforts in communities around the world are diverse and location-specific.”^[15] It follows that our

differing biogeocultural interpretations of the meaning and significance of soil need to be brought into dialogue with one another, and their respective strengths and limitations identified, if we are to build a rich covenantal culture of international land care.

Aldo Leopold vigorously pursued a scientific and ethical critique of what he considered to be the biblically inspired narrative of “Abrahamic land conquest.” It was in counterpoint to this narrative that he generated his alternative narrative of the land ethic and sought *A Sand County Almanac* to communicate the new vision to his fellow citizens.

“We are the landscape,” Iceland’s former president, Vigdis Finnbogadóttir, declared during the Selfoss Forum. The power of the Iceland biogeocultural narrative was apparent in the wood carvings that graced the walls of the Soil Conservation Service headquarters at Gunnarsholt, telling the story of the original promise of the Icelandic Commonwealth 930–1262, the erosion of its land, its prosperity, and its democracy in the subsequent centuries, and the rebirth of the Republic and the efforts to restore the land in the 20th century. It was also apparent in the narrative of the Soil Conservation Service itself, which for a century has worked to realize Hannes Hafstein’s vision, that a time will come when the “land’s wounds are healed.” The Soil Conservation Service of Iceland modeled the principle of “common but differentiated responsibilities” when it decided to convene an International Forum in 2007, where it could contribute the inspiration—and the lessons—of its own history to others working on behalf of soil conservation in many different cultural and environmental contexts and to the common task of finding a way forward for the world as a whole.

Earth Spirituality

Some sympathetic yet critical voices, such as environmental philosopher Strachan Donnelley, have raised the question of whether the existing conceptions of the earth covenant, as reflected in the text of the Earth Charter, have “taken the Earth seriously enough or bound humanity sufficiently to the Earth’s well-being.”^[16]

What Donnelley and others are saying is that to take the earth’s evolution seriously requires accepting the realities of deep time, the dynamics of evolutionary change, basic continuity rather than radical disjunction between “living” and “nonliving,” a geocentric rather than an anthropocentric worldview, the need for protecting a majority of the earth’s surface from human interference if evolution is to continue unimpaired, and a profound personal solidarity and intimacy with the natural world. They discern reluctance in existing discussions of global ethics to forthrightly acknowledge that we are not the reference point of earth’s evolution but mortal creatures who like all creatures are born and die of earthly processes, are absolutely dependent on them for our

sustenance, and are completely bound with them in a common destiny.

Soil is our most direct link to the evolutionary origins of life in the waters of the planet, and the greatest repository we have of the early history of earth's evolution. We—and all other forms of terrestrial life—are absolutely dependent on it. It may well be that a reluctance to appreciate the importance of soil in our lives is due to a reluctance to accept the full spiritual implications of our participation in this reality. If so, then a contribution that soil ethics can make to the earth covenant is to bring this reality to our consciousness and encourage the emergence of an evolutionary spirituality that can celebrate, rather than deplore, our earthly identity.

Many of the great religious traditions of the world have acknowledged this reality. We speak in theology of ultimate reality as the “ground of being.” *Human*, *humility*, and *humus* come from the same ancient Indo-European root meaning “soil.” *Adamah* means soil in Hebrew, and Adam means the “son of soil, formed from the dust of the Earth”; Eve is “the mother of all living” and therefore Adam and Eve literally mean “soil and life.” The Indian Upanishads bear similar understandings. Moreover, as the widely read Agrarian Essayist Wendell Berry reminds us, “soil is the place where death becomes life again.”^[6]

Soil makes clear the meaning of the covenant of being, that all creatures are fellow voyagers in the great ecological and evolutionary odyssey of “dust unto dust.” Soil reveals some of the most important conditions laid down by the creativity in which we participate and upon which all life depends.

CONCLUSION

A new global covenant requires a transformation of our individual and communal commitments so that they are in keeping with truly universal principles of global justice, peace, and sustainability. The post–World War II history of international accords leading to the Earth Charter and the Millennium Development Goals indicates that such a process has begun. But it will take much additional ethical reflection, opportunity for transcultural dialogue, and determined effort by “conscience constituencies” and political and business leaders across the world if it is to be carried forward. Making a true global covenant ultimately requires the participation of every person and society on the planet and the critical reform of every ecological, economic, social, and spiritual relationship of human life.

Increased awareness of our ethical responsibilities to and for the soils of the planet is an essential component in moving this process forward. Not only is responsibility for soil health by every person and community a biophysical precondition of our future existence on the planet and therefore any opportunity we may have to exercise every other form of covenantal responsibility,

but by understanding the special character of our ethical responsibilities for soil we are able to better understand the meaning of all our obligations to one another and the rest of nature. Soil ethics has become a paradigmatic case of what is universally required of us. It is no coincidence that in the English language we employ the same word, “earth,” as a name both for soil and for the planet.

We have examined six ways in which soil ethics lifts into clearer view both our special ethical responsibilities for soil health and our general covenantal responsibilities for sustaining the community of life. We have argued that 1) successful soil policy requires that ecological and social imperatives be addressed together, as a matter of eco-justice; 2) the need for soil integrity demonstrates why ecological integrity must be the *first principle* of our commitment to sustainability; 3) soil stewardship is grounded in intra and intergenerational covenants; 4) the need for precaution in the ways we treat soil reveals the limits of our scientific and practical understanding of how to conserve all the planet's resources; 5) a “common but differentiated” approach to our cultural as well as economic and technological capacities for land care is a foundational principle for global ethics; and 6) our destiny as *humans* and *humus* reveals the evolutionary and spiritual solidarity we experience with all creatures on earth.

We have also suggested several ways in which the Earth Charter's principles may be drawn upon to better understand the content of soil ethics, and conversely, how attention to soil ethics has the potential to enhance the conceptual foundations and practical effectiveness of the Earth Charter. Not least important, in respect to the latter, is the need to address the omission of soil as a major subject in its own right in the text of the Earth Charter and to explicitly recognize our responsibilities for soil health in the global ethics dialogue.

A new covenant with soil is essential for making a new covenant with earth. It is also a test of whether we will be able to succeed in answering the great calling of our age.

Eutrophication

Thomas G. Franti

Department of Biological Systems Engineering, University of Nebraska, Lincoln, Nebraska, U.S.A.

Kyle D. Hoagland

School of Natural Resources, University of Nebraska, Lincoln, Nebraska, U.S.A.

Abstract

Eutrophication is the nutrient enrichment of surface water and the subsequent impacts on water quality and the aquatic ecosystem. Cultural eutrophication is the result of excess nutrients—primarily nitrogen (N) and phosphorus (P)—delivered to rivers, lakes, and estuaries by the activities of humans. The rate of eutrophication is controlled by the rate at which N and P are delivered to a body of water. There are various biological effects of eutrophication. The best way to reduce or reverse eutrophication is to reduce nutrient loading; that is, targeting the source of the problem.

INTRODUCTION

Eutrophication is the nutrient enrichment of surface water and the subsequent impacts on water quality and the aquatic ecosystem. The overabundance of plant nutrients, usually nitrogen and phosphorus—but sometimes silicon, potassium, calcium, iron, or manganese—creates the conditions for excessive plant growth.^[1] Algal blooms are an example of excessive growth caused by the over-supply of nutrients. A body of water is classified by its trophic state based on the amount of nutrients supplied to it. An oligotrophic state is low in nutrients, a mesotrophic state is intermediate, and a eutrophic or hypereutrophic state is high in nutrients.^[2] Eutrophication is a natural process. However, as a natural process, it takes generations, or even thousands of years, for eutrophication to cause significant changes. It is the acceleration of the process, known as cultural eutrophication, which is of the greatest concern to water quality and the health of aquatic systems.

CULTURAL EUTROPHICATION

Cultural eutrophication is the result of excess nutrients—primarily nitrogen and phosphorus—delivered to rivers, lakes, and estuaries by the activities of humans. Nutrient loading can come from both point sources and diffuse sources. Point sources of nutrients are generally urban sewage treatment or industrial water treatment. Diffuse sources (or non-point sources) of nutrients include agriculture, deforestation, and urban lawn runoff. The use of commercial fertilizer in crop production

can lead to losses of nutrients to surface water. Concentrated animal feeding operations are also a potential source of excess nutrients.^[2,3] Finally, deforestation and subsequent soil erosion can deliver excess nutrients, sediment, and organic matter to surface water, creating the conditions for eutrophication.

The natural aging process of lakes in some climates can lead from an oligotrophic state, with clean open water supporting usually cold water fish species, to a eutrophic state of warmer, shallow water supporting different species of plants and fish and, ultimately, to a filled lake closed over by a bog or a fen. This process usually takes thousands of years. In contrast, cultural eutrophication can occur in a matter of one or two generations.

The last 50 years of the 20th century saw the greatest impact of eutrophication on the world's waters. Cultural eutrophication has accelerated the lake aging process, reduced water quality, and impacted aquatic plant and animal populations, at economic costs. These impacts are being felt worldwide.^[1]

Modern society's use of phosphorus additives in detergents has led to excessive phosphorus loading to surface waters.^[1] Modern agriculture's use of commercial fertilizer and fertilizer's relative abundance, low cost, and over use have led to excessive nitrogen loading to surface water. Agriculture also contributes excessive phosphorus from fertilizer and from intensive livestock operations and land application of manure.^[3,4] Urban sources, such as sewage treatment plants, storm water runoff, industrial water treatment facilities, and food processing, contribute excess nutrients. Sewage treatment loading to waters, including treated gray water, is generally considered the greater source of phosphorus.

The greater contributor of nitrogen is agricultural crop production. Other significant agricultural sources are animal confinement operations, forestry, and atmospheric inputs.

RATE OF EUTROPHICATION

The rate of eutrophication is controlled by the rate at which nitrogen and phosphorus are delivered to a body of water. It is generally accepted that phosphorus is the limiting nutrient for algal growth in lakes.^[1,5] Another limiting factor for algal growth is light. As excess phosphorus enters a lake, it can trigger high levels of algal growth. Excessive growth, or blooms, can reduce water clarity. Aquatic macrophytes may also thrive under these conditions. This process can increase the productivity of a lake to an extent. When it becomes excessive, the process of cultural eutrophication has begun.

The nutrients supplied to an aquatic system is the most important factor that determines the species and amount of plant material, which in turn controls available oxygen and the animal species that thrive.^[1] As plants and macrophytes grow and die, organic matter accumulates on the lake bottom. Decomposition of excessive amounts of organic matter can consume available oxygen and create anoxic conditions. An anoxic condition drives away plant and animal species dependent on oxygen. Slowly, a lake's original community changes.

This anoxic state creates another problem if a lake becomes stratified. Temperature differences in the water at the lake's surface and at depth can create thermal stratification. In this condition, the cold, low-oxygen water in the hypolimnion, or lower layer, does not mix with the epilimnion, the warmer surface water. In this condition, the anoxic conditions in the hypolimnion create a condition where the sediment releases phosphorus, which is transported upward to the epilimnion and contributes to increased algal growth. This internal cycling of phosphorus continues the eutrophication process even if no additional phosphorus enters the lake.^[5,6]

EFFECTS OF EUTROPHICATION

There are various biological effects of eutrophication. Besides the problems of algal blooms and anoxic conditions previously described, there are changes in water temperature, reduction in water clarity, increased macrophyte production, population shifts in both plants and animals, and accelerated aging of lakes. Fish kills and the coastal "red tides" and "brown tides" are also potential environmental impacts from eutrophication.^[5,7]

There are many impacts on human use of water from eutrophication. Potable water—water used for human consumption—can be significantly degraded by eutrophication. Besides the excess nutrients themselves, there is

excess algae and other plant growth, which can contribute to unwanted odors and tastes. Thus, additional water treatment is needed to make the water drinkable.^[1,4]

The decline of commercial and recreational fisheries is also an indirect result of eutrophication. Fish populations may move away or over time shift to less desirable fish species as water temperature, clarity, and quality change.^[1]

There are also negative impacts on recreational use of surface waters such as boating and swimming as a result of floating plant growth, smell, and the overall loss of aesthetic quality.^[4] Finally, the general decline of an aquatic ecosystem and the loss of biodiversity are impacts of eutrophication.^[1,3,7]

Some of these impacts can cause significant economic losses as well. Water treatment costs rise as water quality decreases. Algal blooms can contribute to shutting down water treatment plants. Advanced water treatment of municipal water to remove nutrients (such as alum addition)—hence removing a contributing factor to eutrophication—adds another expense to water treatment. Loss of commercial fisheries is an economic impact to a region. Finally, loss of recreation income from tourists, boaters, and recreational fisherman can have significant impacts on a local economy.^[4,7]

REDUCTION AND MANAGEMENT

Two approaches can be taken to the reduction and management of eutrophication: 1) reduction of nutrient loads; and 2) managing the high-nutrient state.^[1] Reduction of loading is clearly the more robust approach. Reduced loads are necessary if long-term improvement is expected. However, because of the ecosystem changes brought on by eutrophication and the potential problem of phosphorus cycling previously described, water quality and ecosystem improvements may not respond quickly to reduced loading.^[3] A combination of reduced loads and in-lake controls may be needed.

Reducing nutrient loads requires reduction of both point and diffuse sources. To reduce point sources, sewage and industrial water treatment plants need advanced water treatment to remove nutrients.^[1,7] Advanced water treatment is expensive, but is the only way to reduce these point source nutrients. Most diffuse sources contributing nutrients to surface water come from agricultural operations. Loading is dependent on the type of crops grown, soil type, climate, cultural practices, fertilizer use, and whether animal waste management practices are sufficient to reduce loading. Nutrient reduction from these sources will require improved management of fertilizer and animal waste and continued reduction of soil erosion throughout the watershed.^[1]

There are several methods used to manage nutrient levels in lakes. These fall into two categories: those that 1) remove nutrients or 2) manage nutrient levels without

nutrient removal. Methods to remove nutrients include the following: 1) lake flushing; 2) hypolimnetic water withdrawal; 3) sediment removal (e.g., dredging); and 4) nutrient inactivation by precipitation (e.g., alum treatment). Methods to manage nutrients without removing them include the following: 1) artificial mixing and/or aeration; 2) dilution by the addition of water low in nutrients; 3) bottom sealing to prevent internal nutrient cycling; 4) manipulation of lake biological communities (e.g., selective fish harvesting or the introduction of fish predators such as largemouth bass, walleye, or brown trout); 5) introduction of biological controls for unwanted macrophyte growth (e.g., weevils or grass carp); and 6) herbicide or other chemical treatments (e.g., copper sulfate) of excessive algal or macrophyte growth.^[1,6]

Clearly, the best way to reduce or reverse eutrophication is to reduce nutrient loading, i.e., targeting the source of the problem.^[1] This long-term solution involves participation and management by people throughout the entire watershed. In-lake nutrient management can be done, but may require annual inputs and regular management.

Evaporation

William P. Kustas

Hydrology and Remote Sensing Lab, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Beltsville, Maryland, U.S.A.

Abstract

Soil evaporation can significantly influence energy flux partitioning of partially vegetated surfaces, ultimately affecting plant transpiration. While important, quantification of soil evaporation, separately from canopy transpiration, is challenging. Techniques for measuring soil evaporation exist and continually improve. The large variability in soil water content requires that there be careful thought to the design of soil evaporation measurements in the field. Numerical models for simulating soil evaporation have been developed and are shown to be fairly robust. However, the required inputs for defining model parameters often limit their application. For many operational applications where detailed soils and ancillary weather data are unavailable or where daily evaporation values are only needed, some of the analytical models described may provide the necessary level of accuracy. Moreover, in the application of weather forecast and hydrologic models, the use of simplified approaches is necessitated by the computational requirements or the lack of adequate data or both for defining more complex numerical model inputs. For large area estimation, the use of remotely sensed soil moisture and surface temperature offer the greatest potential for operational applications.

INTRODUCTION

Soil evaporation not only determines partitioning of available energy between sensible and latent heat flux for bare soil surfaces but can also significantly influence energy flux partitioning of partially vegetated surfaces. This latter effect occurs via the impact of soil evaporation on the resulting surface soil moisture and temperature. These, in turn, strongly influence the microclimate in partially vegetated canopies, indirectly affecting plant transpiration.^[1] Over a growing season, soil evaporation can be a significant fraction of total water loss for agricultural crops.^[2] On a seasonal basis in semiarid and arid regions, soil evaporation can significantly alter the relative fraction of runoff to rainfall, which in turn has a major impact on the available water for plants.^[3] In deserts, in spite of its small magnitude, soil evaporation can introduce significant errors in meteorological forecasting if neglected.^[4]

The measurement of soil evaporation at field scale is typically obtained using standard micrometeorological techniques, namely Bowen ratio and eddy covariance methods. Traditionally, due to fetch and measurement requirements, under partial canopy cover conditions, these techniques are not able to partition the total evapotranspiration into its soil evaporation and plant transpiration components. A novel procedure for partitioning evapotranspiration through utilizing the measured high-frequency time series of carbon dioxide and water vapor concentrations has been developed and tested.^[5] This approach relies upon the simple assumption that

contributions to the time series of carbon dioxide and water vapor concentrations derived from stomatal processes (i.e., photosynthesis and transpiration), and non-stomatal processes (i.e., respiration and direct evaporation) separately conform to flux-variance similarity. Vegetation water use efficiency is the only parameter needed to perform the partitioning. Further work is needed to evaluate the utility of this technique with eddy covariance data collected over a variety of land cover and climate conditions.

Soil evaporation in partial canopy cover conditions varies spatially depending primarily on soil water distribution, canopy shading, and under-canopy wind patterns. These effects are magnified in row crops and under various irrigation techniques (e.g., drip irrigation). Soil evaporation can be measured using microlysimeters,^[6] chambers,^[7] time-domain reflectometers (TDRs),^[8] a combination of microlysimetry and TDR,^[9] micro-Bowen ratio systems,^[3,10] or heat pulse probes.^[11] Given the high spatial variability in the driving forces under partial canopy cover conditions, these point-based measurements are difficult to extrapolate to the field scale. Therefore, models have been developed to estimate the contribution of soil evaporation to the total evapotranspiration process.

Measurement methods are described, and models of varying degrees of complexity are reviewed, focusing primarily on relatively simple analytical models, some of which provide daily estimates and can be implemented operationally. The potential application of models using remote sensing data for large-scale estimation is also briefly discussed.

METHODOLOGIES

Measurement Methods

Microlysimeters

Microlysimeters have been widely used to measure evaporation from the soil surface of irrigated crops.^[8,12,13] Typically, an undisturbed soil sample (a representative vertical section of the soil profile) is inserted into a small cylinder open at the top. The microlysimeter is inserted back into the soil with its upper edge level with the soil surface and weighed either periodically or continuously. Changes in weight reflect an evaporative flux. To eliminate vertical heat conduction through the microlysimeter cylinder and minimize horizontal heat flux in the deeper layers of the sample, poly(vinyl chloride) (PVC) has been found to be the most suitable material. The microlysimeter's dimensions are typically a diameter of ~8 cm and a depth of 7–10 cm.^[14–16] Theoretically, the microlysimeters provide absolute reference for soil evaporation, as long as their soil and the heat balance are similar to the surrounding area.

Chambers

Chambers are used to directly measure the flux of gases between the soil surface and the atmosphere by enclosing a volume and measuring all flux into and out of the volume.^[17] Reviews of chamber designs and calculations of fluxes based on chamber methods can be found in Livingston and Hutchinson^[18] and Hutchinson and Livingston.^[19]

With infrared gas analyzers (IRGAs) becoming increasingly common, they are widely considered to be the method of choice for chamber-based soil respiration and evaporation measurements.^[20] Chambers can be used in either of two modes to calculate fluxes:^[18] 1) in steady-state mode, the flux is calculated from the concentration difference between the air flowing at a known rate through the chamber inlet and outlet after the chamber headspace air has come to equilibrium concentration of carbon dioxide and 2) in the non-steady-state mode, the flux is calculated from the rate of increasing concentration in the chamber headspace of known volume shortly after the chamber is put over the soil.

In both modes, air is circulated between a small chamber that is placed on the soil and an IRGA. Typically, a soil chamber of ca. 1 L volume is placed on a PVC collar of about 80 cm² area. This collar is inserted about 2 cm into the soil and secured to prevent movement when the chamber is placed on it. When the chamber is placed on the collar, circulation of air between the chamber and the external IRGA is induced by a pump, and the water vapor concentration is measured.^[21]

Soil water balance

Soil evaporation (E) can be extracted from the water balance equation, provided that all other components are known

$$E = I + P - R + F - \Delta S \quad (1)$$

where I is irrigation, P is precipitation, R is runoff or runoff, F is deep soil water flux (percolation), and ΔS is change in soil water storage. For an experimental field site, irrigation and precipitation can be easily monitored, and runoff and runoff may be controlled to near-zero amounts by diking. Deep soil water flux errors can be reliably estimated in several ways, with the most important being the monitoring or measuring of the soil water content well below the root zone. The change in soil water storage can be determined fairly accurately with profile measurements of soil water content over multiple depths at the beginning and end of a defined time period.

There are many soil water content sensors, all of which work by measuring a surrogate property that is empirically or theoretically related to the soil water content. A comparative review by Evett et al.^[22] concluded that soil water content is best determined using the neutron probe, gravimetric sampling, and conventional TDR^[23] methods as compared to bore hole capacitance methods. Of the three optimal methods in the study, TDR is the only methodology capable of providing automated continuous measurements. However, other continuous measurement sensors such as frequency-domain reflectometers (FDRs),^[24] and time-domain transmission^[25] sensors are also emerging as options for long-term installations, given appropriate calibration.

Micro-Bowen ratio systems

The Bowen ratio energy balance (BREB) approach is one of the simplest and most practical methods of estimating water vapor flux^[10,26] and has thus been used extensively under a wide range of conditions providing robust estimates.^[27] Use of the BREB concept^[28] enables solving the energy balance equation by measuring simple gradients of air temperature and vapor pressure in the near-surface layer above the evaporating surface. The BREB equation is

$$LE = \frac{R_N - G}{1 + B_o} \quad (2)$$

in which LE is the latent heat flux, R_N is the net radiation, G is the soil heat flux, and B_o the Bowen ratio, which is found from measurements of temperature and vapor pressure at two heights within the constant flux layer.^[29] Assuming equal transfer coefficients for heat and vapor, the Bowen ratio is defined as

$$B_o = \frac{H}{LE} = \gamma \frac{\partial T}{\partial e} \quad (3)$$

where H is the sensible heat flux, γ is the psychrometric constant, T is the air temperature, and e is the water vapor pressure.

Application of the Bowen ratio concept to measure bare soil surface evaporation was suggested^[3,10] by measuring temperature and vapor pressure close to the soil surface (e.g., at 1 and 6 cm). Compared to microlysimeters, the micro-Bowen ratio (MBR) system yielded good results over bare soil.^[10] The potential of the MBR approach was demonstrated by successfully measuring soil evaporation within a maize field.^[30] The testing of the MBR is very limited, and further research is required to examine the performance of the technique under various environmental and agronomic conditions.

Heat pulse probes

A novel approach for measuring soil evaporation has been proposed, based on the soil sensible heat balance.^[11,31] In this approach, a sensible heat balance is used to determine the amount of latent heat involved in the vaporization of soil water following Gardner and Hanks.^[32]

$$LE = (H_0 - H_1) - \Delta S \quad (4)$$

where H_0 and H_1 are soil sensible heat fluxes at depths 0 and 1, respectively; ΔS is the change in soil sensible heat storage between depths 0 and 1; L is the latent heat of vaporization; and E is evaporation.

Typically, three-needle sensors like those described by Ren et al.^[33] are used, which are spaced 6 mm apart, in parallel. Temperature is measured by all three needles, and the central needle also contains a resistance heater for producing a slight pulse of heat required for the heat pulse method. At a given time interval (2–4 hours), a heat pulse is executed, and the corresponding rise in temperature at the outer sensor needles is recorded. Soil volumetric heat capacity and thermal diffusivity are then determined from the heat input and temperature response following the procedures described by Knight and Kluitenberg^[34] and Bristow et al.,^[35] respectively. Having measurements of soil temperature, thermal conductivity, and volumetric heat, evaporation is estimated from Eq. 4.

Numerical Models

Numerous mechanistic/numerical models of heat and mass flows exist and are primarily based on the theory of Philip and de Vries.^[36] However, they continue to be refined through improved parameterization of the moisture and heat transport through the soil profile.^[37–39] Some of these mechanistic models have been used to explore the utility of bulk transfer approaches used in weather forecasting models^[40] and in soil–vegetation–atmosphere models.^[41]

computing field to regional-scale fluxes. These bulk transport approaches are commonly called the “alpha” and “beta” methods defined by the following expressions

$$LE_s = \frac{\rho C_p}{\gamma} \left(\frac{ae_*(T_s) - e_A}{R_A} \right) \quad (5)$$

and

$$LE_s = \frac{\rho C_p}{\gamma} \beta \left(\frac{e_*(T_s) - e_A}{R_A} \right) \quad (6)$$

where r is the air density ($\sim 1 \text{ kg/m}^3$), C_p the heat capacity of air ($\sim 1000 \text{ J/kg/K}$), γ the psychrometric constant ($\sim 65 \text{ Pa}$), $e_*(T_s)$ the saturated vapor pressure (Pa) at soil temperature T_s (K), e_A the vapor pressure (Pa) at some reference level in the atmosphere, and R_A is the resistance (s/m) to vapor transport from the surface usually defined from surface layer similarity theory.^[42] For a, several different formulations exist^[43,44] with one of the first relating a to the thermodynamic relationship for relative humidity in the soil pore space,^[45]

$$h_R = \exp \left(\frac{\psi g}{R_V T_s} \right) \quad (7)$$

where ψ is the soil matric potential (m), g the acceleration of gravity (9.8 m/s^2), and R_V the gas constant for water vapor (461.5 J/kg/K). From Eq. 6, β can be defined as a ratio of aerodynamic and soil resistance to vapor transport from the soil layer to the surface, R_s , namely

$$\beta = \frac{R_A}{R_A + R_s} \quad (8)$$

Both modeling^[44] and observational results^[46,47] indicate that more reliable results are obtained using the beta method. In fact, Ye and Pielke^[44] formulate an expression similar to Camillo and Gurney,^[48] which combines Eqs. 5 and 6 and provides more reliable evaporation rates for a wider range of conditions,

$$LE_s = \frac{\rho C_p}{\gamma} \beta \left(\frac{ae_*(T_s) - e_A}{R_A} \right) \quad (9)$$

Unfortunately, there is no consensus concerning the depth in the soil profile to consider in defining the a and b terms. In particular, studies evaluating the soil resistance term R_s use a range of soil moisture depths: 0–1/2 cm,^[48] 0–1 cm,^[7] 0–2 cm,^[39,46] and 0–5 cm.^[39] The study conducted by Chanzy and Bruckler^[38] appears to be one of the few studies that attempts to determine the most useful soil moisture depth for modeling soil evaporation by considering the penetration depth of passive microwave sensors of varying wavelengths. Using field data and numerical simulations with a mechanistic model, they find that the 0–5 cm depth, which can be provided by the L-band microwave frequency, appears to be the most adequate frequency for evaluating soil evaporation.

Table 1 Bulk soil resistance formulations, R_S , from previous studies.

R_S formula (s/m)	Value of coefficients	Soil type	Depth (cm)	References
$R_S = a \left(\frac{\theta_s}{\theta} \right)^n + b$	$a = 3.5$ $b = 33.5$ $n = 2.3$	Loam ^a	0–1/2	[21]
$R_S = a(\theta_s - \theta) + b$	$a = 4,140$ $b = -805$	Loam ^b	0–1/2	[48]
$R_S = R_{S\text{MIN}} \exp[a(\theta_{\text{MIN}} - \theta)]$	$R_{S\text{MIN}} = 10 \text{ s/m}$ $\theta_{\text{MIN}} = 15\%$ $a = 0.3563$	Fine sandy loam	0–1	[7]

^aSoil type for the data from Jackson et al.^[49] was determined from texture-dependent soil hydraulic conductivity and matric potential equations of Clapp and Hornberger evaluated by Camillo & Gurney.^[48]

^bSoil type was determined from texture-dependent soil hydraulic conductivity and matric potential equations of Clapp and Hornberger evaluated by Sellers et al.^[41]

Besides the depth of the soil layer to consider, the equations relating soil moisture to R_S have ranged from linear to exponential (Table 1). Furthermore, observations and numerical models have shown that it varies significantly throughout the day and that its magnitude is also affected by climatic conditions.^[38,39]

These are not the only complicating factors that make the use of such a bulk resistance approach somewhat tenuous. From detailed observations of soil moisture changes and water movement, Jackson et al.^[49] found the soil water flux in the 0–9 cm depth to be very dynamic with fluxes at all depths continually changing in magnitude and sometimes direction over the course of a day. These phenomena observed by Jackson et al.^[49] are owing in part to a process that occurs during soil drying where dry surface soil layer forms, significantly affecting the vapor transport through the profile.^[50] Yamanaka et al.^[51] developed and verified, using wind tunnel data, a simple energy balance model in which the soil moisture available for evaporation is defined using the depth of the evaporating/drying front in the soil. This approach removes the ambiguity of defining the thickness of the soil layer and resulting moisture available for evaporation. However, the depth of the evaporating surface is not generally known *a priori* nor can it be measured in field conditions; hence, this approach is

limited to exploring the effects of evaporating front on R_S type formulations.

Analytical Models

To reduce the effect of temporal varying, R_S , Chanzy and Bruckler^[38] developed a simple analytically based daily LE_S (E_D) model using simulations from their mechanistic model for different soil texture, moisture, and climatic conditions as quantified by potential evaporation (E_{PD}), as given by Penman.^[52] The analytical daily model requires midday 0–5 cm soil moisture θ , daily potential evaporation, and daily average wind speed (U_D). The simple model has the following form:

$$\frac{E_D}{E_{PD}} = \left[\frac{\exp(A\theta + B)}{1 + \exp(A\theta + B)} \right] C + (1 - C) \quad (10)$$

$$A = a + 5\max(3 - E_{PD}, 0) \quad (11)$$

$$B = b - 5(-0.025b - 0.05) \max(3 - E_{PD}, 0) + \alpha(U_D - 3) \quad (12)$$

$$C = 0.90 - 0.05c(U_D - 3) \quad (13)$$

Fig. 1 A plot of E^D/E^{PD} , estimated using Eq. 10 vs. volumetric water content for (A) loam and (B) silty clay loam soil under two evaporative demand conditions: $U^D = 1$ m/sec and $E^{PD} = 2$ mm/day (squares) and $U^D = 5$ m/sec and $E^{PD} = 10$ mm/day (diamonds).

Source: From Chanzy & Bluckler.^[38]

where the coefficients a , b , and c depend on soil texture (Table 1) and were derived from their detailed mechanistic model simulations for loam, silty clay loam, and clay soils.^[38] In Fig. 1, a plot of Eq. 10 is given for two soil types, loam (Fig. 1A) and silty clay loam (Fig. 1B) under two climatic conditions, namely, a relatively low evaporative demand condition with $U_D = 1$ m/s and $E_{PD} = 2$ mm/day and high demand $U_D = 5$ m/s and $E_{PD} = 10$ mm/day. Notice the transition from $E_D/E_{PD} \sim 1$ to $E_D/E_{PD} < 1$ as a function of θ varies not only with the soil texture but also with the evaporative demand. The simplicity of such a scheme outlined in Eq. 10 needs further testing for different soil textures and under a wider range of climatic conditions.

The ratio E_D/E_{PD} as a function of θ illustrated in Fig. 1 also depicts the effect of the two “drying stages” typically used to describe soil evaporation.^[42] The “first stage” (S₁) of drying is under the condition where water is available in the near-surface soil to meet atmospheric demand, i.e., $E_D/E_{PD} \sim 1$. In the “second stage” (S₂) of drying, the water availability or θ falls below a certain threshold where the soil evaporation is no longer controlled by the evaporative demand, namely, $E_D/E_{PD} < 1$. Under S₂, several studies

find that a simple formulation can be derived by assuming that the time change in θ is governed by desorption, namely, as isothermal diffusion with negligible gravity effects from a semi-infinite uniform medium. This leads to the rate of evaporation for S₂ being approximated by^[42,53]

$$E_D = 0.5D_E t^{-1/2} \quad (14)$$

where the desorptivity D_E (mm/day^{1/2}) is assumed to be a constant for a particular soil type and t is the time (in days) from the start of S₂. Although both numerical models and observations indicate that the soil evaporation is certainly a more complicated process than the simple analytical expression given by Eq. 14, a number of field studies^[3,54–58] have shown that for S₂ conditions, reliable daily values can be obtained using Eq. 14. In many of these studies for determining D_E , the integral of Eq. 14 is used, which yields the cumulative evaporation as a function of $t^{1/2}$

$$\sum E_D = D_E(t - t_0)^{1/2} \quad (15)$$

where t_0 is the number of days where $E_D/E_{PD} \sim 1$ or is in S₁. In practice, observations of $\sum E_D$ are plotted vs. $(t - t_0)^{1/2}$, and in many cases the choice of the starting point of S₂ is $t_0 \approx$ or immediately after the soil is saturated. As shown by Campbell and Norman,^[58] the course of evaporation rate for three drying experiments (see Fig. 9. 6 in Campbell and Norman^[58]) indicates that for a loam soil, t_0 depends on the evaporative demand or E_{PD} with $t_0 \sim 2$ days when E_{PD} is high vs. $t_0 \sim 5$ days when E_{PD} is low. On the other hand, for a sandy soil, there is almost an immediate change from S₁ to S₂ conditions with $t_0 \approx 1$ day. As suggested by the analysis of Jackson et al.^[56] and as stated more explicitly by Brutsaert and Chen,^[59] the value of t_0 can significantly influence the value computed for D_E . Jackson et al.^[56] also show that for the same soil type, the value of D_E has a seasonal dependency (ranging from 4 to 8 mm/day^{1/2}) most likely related to the evaporative demand, which they correlate to daily average soil temperature (see Fig. 2 in Jackson et al.^[56]). Values of D_E from the various studies are listed in Table 2. Brutsaert and Chen^[59] modified Eq. 14 for deriving D_E by rewriting in terms of a “time-shifted” variable $T = t - t_0$ and expressing it in the form

$$E_D^{-2} = \left(\frac{2}{D_E}\right)^2 T \quad (16)$$

where D_E and t_0 will come from the slope and intercept (see Fig. 1 in Brutsaert and Chen^[59]). It follows that $\sum E_D$ under S₂ will start at $T = T_0$ and not at $T = 0$, so that Eq. 15 is rewritten as

$$\sum E_D = D_E(T^{1/2} - T_0^{1/2}) \quad (17)$$

They evaluated the effect on the derived D_E using this technique with the data from Black et al.^[54] The value of

Table 2 Values of desorptivity, D_E , evaluated from various experimental sites.

Desorptivity D_E (mm/day ^{1/2})	Soil type	References

2.11	Gravelly sandy loam	[3]

^aThe magnitude of D_E was found to have a seasonal dependency.

^bSoil type was determined from texture-dependent soil hydraulic conductivity and matric potential equations of Clapp and Hornberger evaluated by Camillo and Gurney.^[48]

^cThis value was evaluated for a vegetated surface.

^dSoil type was determined from texture-dependent soil hydraulic conductivity and matric potential equations of Clapp and Hornberger evaluated by Sellers et al.^[41]

D_E using Eqs. 16 and 17 was estimated to be approximately 3.3 mm/day^{1/2}, which is smaller than D_E values reported by Black et al.,^[54] namely, 4.3–5 mm/day^{1/2}. However, Brutsaert and Chen^[59] show that this technique yields a better linear fit to the data points that were actually under S₂ conditions.

Equations 16 and 17 were used with the September 1973 data set from Jackson et al.^[56] and compared to using Eq. 15 with $t_O = 0$. The plot of Eq. 15 with the regression line in Fig. 2 yields $D_E \sim 10$ mm/day^{1/2}, which is significantly larger than any previous estimates (Table 2). Moreover, it is obvious from the figure that Eq. 15 should not be applied with $t_O = 0$, as this relationship is not linear over the whole drying processes. With Eq. 16, applied to the data, t_O is estimated to be approximately 4.3 days, and thus a linear

**Fig. 2** The desorptivity D_E (mm/day^{1/2}) estimated from a least squares linear fit to the data assuming $t_O = 0$ (i.e., stage-two drying occurs immediately after irrigation/precipitation).

**Fig. 3** Estimation of (A) D_E and t_O with the data from Fig. 2 using Eq. 16 and (B) the resulting cumulative evaporation ΣE_D curve under second stage drying using Eq. 17.

Source: From Brutsaert & Chen.^[59]

relationship should start at the shifted time scale $T = t - 4.3$; this means ΣE_D should start on day 5 or $T_O \approx 5 - 4.3$ (Fig. 3A). With Eq. 17, a more realistic $D_E \approx 4.6$ mm/day^{1/2} is estimated for the linear portion of daily evaporation following the S₂ condition (Fig. 3B).

While this approach is relatively easy to implement operationally, D_E will likely depend on climatic factors as well as soil textural properties. However, it might be feasible to describe the main climate/seasonal effect on D_E from soil temperature observations.^[56] These might come from weather station observations or possibly from multitemporal remote sensing observations of surface temperature.

The difficulty in developing a formulation for R_S , which correctly describes the water vapor transfer process in the soil, was recognized much earlier by Fuchs and Tanner^[60] and Tanner and Fuchs.^[61] They proposed a combination method instead that involves atmospheric surface layer observations and remotely sensed surface temperature, T_{RS} . Starting with the energy balance equation

$$R_N = H + G + LE \quad (18)$$

where R_N is the net radiation, H the sensible heat flux, LE the latent heat flux, and G the soil heat flux all in W/m², and assuming the resistance to heat and water vapor transfer are similar yielding,

$$H = \rho C_p \left(\frac{T_{RS} - T_A}{R_A} \right) \quad (19)$$

$$LE = \frac{\rho C_p}{\gamma} \left(\frac{e_{RS} - e_A}{R_A} \right) \quad (20)$$

an equation of the following form can be derived

$$LE = \left(\frac{\gamma + \Delta}{\Delta} \right) LE_p - \frac{\rho C_p}{\Delta} \left(\frac{e_*(T_{RS}) - e_A}{R_A} \right) \quad (21)$$

where

$$LE_p = \rho C_p \left(\frac{e_*(T_A) - e_A}{R_A(\Delta + \gamma)} \right) + \Delta \left(\frac{R_N - G}{\Delta + \gamma} \right) \quad (22)$$

The difference $e_*(T_A) - e_A$ is commonly called the saturation vapor pressure deficit, and the value of soil surface vapor pressure e_{RS} is equal to $h_{RS}e_*(T_{RS})$ where h_{RS} is the soil surface relative humidity. Substituting Eq. 21 into Eq. 22 yields

$$LE = R_N - G - \frac{\rho C_p}{\Delta} \left(\frac{e_*(T_{RS}) - e_*(T_A)}{R_A} \right) \quad (23)$$

This equation has the advantage over the above bulk resistance formulations using R_S in that there are no assumptions made concerning the saturation deficit at or near the soil surface or how to define h_{RS} . Instead, this effect is accounted for by T_{RS} because as the soil dries, T_{RS} increases and hence $e_*(T_{RS})$, which generally results in the last term on the right-hand side of Eq. 23 to increase, thus causing LE to decrease. In a related approach,^[62] the magnitude of LE is simply computed as a residual in the energy balance equation, Eq. 21, namely,

$$LE = R_N - G - \rho C_p \left(\frac{T_{RS} - T_A}{R_A} \right) \quad (24)$$

Particularly crucial in the application of either Eqs. 23 or 24 is a reliable estimate of R_A and T_{RS} . Issues involved in correcting radiometric temperature observations for surface emissivity, viewing angle effects, and other factors are summarized in Norman and Becker.^[63] The aerodynamic resistance R_A is typically expressed in terms of Monin–Obukhov similarity theory^[42]

$$R_A = \frac{\left\{ \ln \left[\frac{z - d_0}{z_{OM}} \right] - \psi_M \right\} \left\{ \ln \left[\frac{z - d_0}{z_{OS}} \right] - \psi_S \right\}}{k^2 U} \quad (25)$$

where z is the observation height in the surface layer (typically 2–10 m), d_0 the displacement height, z_{OM} the momentum roughness length, z_{OS} the roughness length for scalars (i.e., heat and water vapor), k (~ 0.4) von Karman's constant, ψ_M the stability correction function for momentum, and ψ_S the stability correction function for scalars. Both d_0 and z_{OM} are dependent on the height and density of the roughness obstacles and can be considered a constant

for a given surface, while the magnitude of z_{OS} can vary for a given bare soil surface as it is also a function of the surface friction velocity.^[42] Experimental evidence suggests that existing theory with possible modification to some of the “constants” can still be used to determine z_{OS} providing acceptable estimates of H for bare soil surfaces. However, application of Eq. 24 in partial canopy cover conditions has not been successful in general because z_{OS} is not well defined in Eq. 25, exhibiting large scatter with the existing theory.^[64]

For this reason, estimating soil evaporation from partially vegetated surfaces using T_{RS} invariably has to involve “two-source” approaches, whereby the energy exchanges from the soil and vegetated components are explicitly treated.^[65] Similarly, when using remotely sensed soil moisture for vegetated surfaces, a two-source modeling framework needs to be applied.^[66] In these two-source approaches, there is the added complication of determining aerodynamic resistances between soil and vegetated surfaces and the canopy air space. Schematically, the resistance network and corresponding flux components for two-source models are shown in Fig. 4. An advantage with the two-source formulation of Norman et al.^[65] is that R_S is not actually needed for computing LE_s as it is solved as a residual. Nevertheless, the formulations in such parameterizations that are used (such as the aerodynamic resistance formulations) are likely to strongly influence LE_s values.^[1]

Fig. 4 A schematic diagram illustrating the resistance network for the two-source approach where the subscript c refers to the vegetated canopy and s refers to the soil surface. The symbol $T_R(\theta)$ refers to a radiometric temperature observation at a viewing angle θ , T_{AC} is the model-derived within-canopy air space temperature, h_C is the canopy height, f_C is the fractional vegetation/canopy cover, and R_{AC} and R_{AS} are the aerodynamic resistances to sensible heat flux from the canopy and soil surface, respectively. The main meteorological inputs required for the model are also illustrated, namely wind speed, U , air temperature, T_A , and the net radiation, R_N .

Source: Adapted from Norman, Kustas, et al.^[65]

Yet this two-source formulation is found to be fairly robust in separating soil and canopy contributions to evapotranspiration.^[67]

CONCLUSION

Techniques for measuring soil evaporation, separately from plant transpiration, exist and continually improve. Given the high variability in soil water content often exhibited in the field, the exact position of the instrumentation may have a large effect on the measurement. This is magnified in row crops, where the variability is structured, rather than random. In row crops, soil evaporation is not only dependent on the soil properties, but also local climatic conditions, and the timing of irrigation/precipitation. Under low-to-moderate wind speed conditions (~ 1 to 4 m sec^{-1}), row orientation relative to the wind direction also affects the amount of soil evaporation.^[68] This large variability requires that there be careful thought to the design of soil evaporation measurements in the field. The methodology proposed by Scanlon and Kustas^[5] using eddy covariance measurements suffers less from the sampling issue but requires *a priori* knowledge of the vegetation water use efficiency, which will vary with vegetation type and condition.

For many landscapes having partial vegetative cover, the contribution of soil evaporation to the total evapotranspiration flux cannot be ignored, particularly with regard to the influence of surface soil moisture and temperature on the microclimate in the canopy air space (Fig. 4). Numerical models for simulating soil evaporation have been developed and are shown to be fairly robust. However, the required inputs for defining model parameters often limit their application to field sites having detailed soil profile information and that are well instrumented with ancillary weather data.

For many operational applications, where detailed soil and ancillary weather data are unavailable or where daily evaporation values are only needed, some of the analytical models described may provide the necessary level of accuracy. Moreover, in the application of weather forecast and hydrologic models, the use of simplified approaches is necessitated by the computational requirements or the lack of adequate data or both for defining more complex numerical model parameters and variables.

For large area estimation, the use of remotely sensed soil moisture and surface temperature offers the greatest potential for operational applications. Development of modeling schemes that can incorporate this remote sensing information and readily apply it on a regional scale basis has been proposed and shows promise.^[66,69–71]

Evolution: Soil Seed Bank

Paul B. Cavers

Plant Sciences, University of Western Ontario, London, Ontario, Canada

David Susko

Environmental Science, Department of Natural Sciences, University of Michigan at Dearborn, Dearborn, Michigan, U.S.A.

Abstract

The number and composition of plant seeds found within the soil in a given unit of area comprises the soil seed bank. Seed banks can be incredibly large, often consisting of hundreds to hundreds of thousands of seeds per square meter in a variety of different habitats and communities around the world. These seeds can be short- or long-lived. Seed banks provide a “memory” of prevailing site conditions, as well as climatic and edaphic conditions present many years or decades earlier. Hence, much of the genetic diversity of plant populations is preserved in seed banks. Furthermore, as seeds age in the soil, mutations accumulate and novel variation is introduced into a population. Soil seed banks play a pivotal role in the formation, maintenance, and evolution of plant communities.

INTRODUCTION

The development of the concept of the soil seed bank is generally attributed to Harper.^[1] He separated the typical “bank” into a “deposit account,” consisting of seeds in a dormant state and a “current account,” consisting of non-germinated seeds “in which the only hindrance to immediate germination is a shortage of water and a favorable temperature.” The first use of the term “seed bank” is attributed to Sarukhán.^[2] Over the 20th century, there have been hundreds of studies of seed banks made in a variety of terrestrial and aquatic habitats. Seed banks can be incredibly complex; often with hundreds of different species distributed heterogeneously, with few to hundreds of thousands of seeds per species in each square meter of soil and with great variability in dormancy and longevity, even among the seeds of a single species. Our understanding of this complexity is far from complete.^[3]

SIZES OF SEED BANKS IN DIFFERENT HABITATS AND REGIONS

The numbers of seeds in seed banks can be determined by 1) extraction of seeds followed by identification and counting or 2) identification and counting of seedlings arising from soil samples put under controlled conditions in greenhouses or growth rooms. There are problems with both approaches.^[4] Seed extraction is laborious and may miss small or cryptically colored seeds; additionally, some viable seeds can die before subsequent germination tests. Counts of seedlings, the preferred method in most studies,^[5] will

miss seeds that are alive but unable to germinate under the conditions provided. For the most abundant species, there is usually a good correlation between the two procedures.^[4]

Fenner^[6] summarized the reports on the numbers of seeds found in a wide range of communities; 10^2 – 10^3 m⁻² for forest soils, 10^3 – 10^6 m⁻² for grasslands, and 10^3 – 10^5 m⁻² for arable soils. Arable and disturbed soils often have huge seed banks,^[5] but seed numbers in arable soils have declined as use of chemical herbicides has increased.^[7] Wet sites and marshlands can have enormous seed banks as well.^[8] Baskin and Baskin^[9] presented data on seed banks for 78 disparate communities. In general, their values fell into the ranges described by Fenner, but they cited several forests and grasslands with seed banks having <10 seeds m⁻² vs. up to 646,000 seeds m⁻² in arable land.

SEED LONGEVITY IN THE SOIL

Two well-known experiments, one started by Beal in 1879^[10] and the second by Duvel in 1905,^[11] have shown that the seeds of some plant species can remain dormant for decades, and that crop seeds have the shortest longevity, on average, and weed seeds the greatest. Since then, there have been numerous reviews of seed longevity in seed banks. Baskin and Baskin^[9] separated seed bank studies into 1) those with freshly collected seeds that are buried for specified periods before testing and 2) those that infer the age of buried seeds by dating material in the soil around them.

Studies in which fresh seeds have been buried for various lengths of time are numerous but very few of them have extended beyond 10 years.^[9] Beal’s experiment is still

continuing,^[10] but numbers of seeds per sample are small, and only one set of storage conditions was used. None of the other studies exceeds 40 years, and only two continuing studies are designed to reach 50 years.^[9] There is a great need for large, long-term, comprehensive studies of this type.

In studies of known-age seeds, the decrease in seed numbers over time generally follows the pattern of an exponential decay curve; a constant percentage being lost each year through death and germination.^[5] Seed dormancy overcomes and germination is initiated by many factors. Among the most important are light (including quality, quantity, and daylength), diurnally alternating temperatures, wet stratification at chilling temperatures (0–6°C), and soil nutrients, especially nitrogen (nitrate) levels.^[9]

VARIABILITY IN SEED BANKS IN TIME AND SPACE

Seed banks are more complex than communities of growing plants, primarily because they contain species that are not present as growing plants and because species found as growing plants have additional genotypes present in the seed bank. In addition, seed banks are variable over time and space.

Variability in Time

When viable seeds are retrieved from the seed bank, they can be classified as either: 1) able to germinate when exposed to favorable conditions; or 2) remaining dormant when exposed to a favorable germination regime.^[12] Many fresh seeds fall into the latter category, but this dormancy is often lost after a few weeks or months.^[12] Furthermore, unfavorable environmental conditions, such as high summer temperatures or drought, can return seeds from the former to the latter category.

Thompson and Grime^[12] made an important distinction by classifying the seed banks of individual species as either: 1) “transient,” lasting for less than 1 year and consequently with periods each year when no viable seeds are available to replace or reinforce the plant population; or 2) “persistent” lasting for more than 1 year with remaining seeds overlapping fresh inputs each year. Thompson and Grime^[12] produced four models of seed banks, two transient and two persistent, which have been used as the basis for comparison in many subsequent articles.

Variability in Space

One of the greatest problems facing an investigator of seed banks is how to estimate accurately their sizes, given the unknown and notoriously heterogeneous distribution of seeds, both laterally and at different depths in the soil.^[13,14] For example, the number of seeds per unit area declines

rapidly with increasing depth in the soil.^[9,15] Further, seeds buried at greater depths tend to remain dormant longer, but fewer of them can germinate and emerge successfully to become established seedlings.^[15]

SEED BANK GENETICS

The offspring of plant genotypes that existed may be preserved together in the soil, since seed banks can retain non-germinating but viable seeds for many years or even centuries. Hence, the majority of genetic variation present in a plant population (i.e., the gene pool) is often contained within the seed bank, particularly in short-lived species with long-lived persistent seed banks, while only a fraction of this total variation is present in surface plants at any given date.

Levin^[16] summarized the genetic consequences of a persistent seed bank on a population's gene pool. First, a seed bank maintains the genetic composition of a population and buffers it from extinction by increasing the effective population size, even when plant population size fluctuates dramatically over time.^[17] For instance, the genotypes of surface plants that fail to reproduce before they die may still be present in the seed bank. Second, the seed bank slows the rate of response of seedling or adult plant characters to selection, since gene loci not directly related to seed dormancy are constrained as much as those that influence dormancy. The degree of evolutionary retardation is dependent on seed longevity in the seed bank; retardation is greater in species with long-lived seeds than in those with short-term seed viability, because of the increased genetic load in seed banks containing long-lived seeds.^[18] Third, selection is biased toward traits associated with years of high seed production. As a consequence, the seed bank can serve as an evolutionary filter, where seeds from years of large seed crops may be favored by selection over seeds from years of small seed crops.^[19] Lastly, seed banks may be sources of novel genetic variation. Levin^[16] noted that as seeds age, seed viability declines, whereas chromosome damage and the frequency of mutations within seeds increase. If such mutations are not lethal and can be transmitted to future generations, then the potential for plant populations to evolve may be increased due to the presence of a persistent seed bank.

Empirical studies have compared the amount and distribution of genetic variation in seed banks and surface plants. Typically, such comparisons among seeds of different ages within the seed bank, or among seeds in the soil vs. surface plants are made either 1) by examining morphological or physiological traits of genotypes when grown in common and multiple environment experiments^[20] or 2) by analyzing polymorphic allozyme and isozyme loci using starch gel electrophoresis.^[21–23] From the former technique, consistent phenotypic differences were found among seedlings arising from young (recently buried) and old seeds in the

seed bank when the plants were grown at different densities, temperatures, and nutrient levels.^[20] These results indicated genetic differences between seeds of different ages, but our understanding of the causal mechanisms of such differences is incomplete.

Studies using electrophoretic techniques have shown, in general, that allele frequencies in seed banks differ significantly from those in surface plants,^[21–23] but one study found little differentiation.^[17] Furthermore, many of these studies have found greater homozygosity in the seed bank than in later stages of the life cycle.^[21–23] These results suggest that the genotypes of surface plants constitute only a genetic subpopulation of the gene pool present in the soil seed bank. Hence, seed banks may be particularly important for the persistence and/or recovery of rare and endangered plant species. Presumably, susceptibility to genetic drift and inbreeding depression in small, scarce populations could be mediated by the presence of a homogeneously distributed, genetically diverse reserve of seeds. Examples of such mediation are few, but a study on the rare annual *Clarkia springvillensis* by McCue and Holtsford^[23] supports this argument.

CONCLUSION

The number and composition of plant seeds found within the soil in a given unit of area comprises the soil seed bank. Seed banks can be incredibly large, often consisting of hundreds to hundreds of thousands of seeds per square meter in a variety of different habitats and communities around the world. Also, these seeds can be short- or long-lived. Seed banks provide a “memory” of prevailing site conditions, as well as climatic and edaphic conditions present many years or decades earlier. Hence, much of the genetic diversity of plant populations is preserved in seed banks. Furthermore, as seeds age in the soil, mutations accumulate and novel variation is introduced into a population. It is clear from the accumulated information in this entry that soil seed banks play a pivotal role in the formation, maintenance, and evolution of plant communities.

Fauna

Mary C. Savin

Department of Crop, Soil, and Environmental Sciences, University of Arkansas, Fayetteville, Arkansas, U.S.A.

Abstract

Soil fauna are diverse, abundant, and critical to ecosystem functions. Soil fauna account for almost one-quarter of living species and facilitate important ecological interactions that contribute to decomposition, nutrient cycling, and stabilization of terrestrial ecosystems. Soil fauna are composed of diverse groups of organisms that range across orders of magnitude in size, with many less than a few centimeters or even a few millimeters. These organisms function under different abiotic conditions and, despite their small size, contribute to characteristics and processes observable at field and landscape scales. Research efforts that build upon past discoveries should enhance the understanding of how soil fauna connect aboveground and belowground ecology for proper management and sustainability of ecosystems and ecosystem services.

INTRODUCTION

Soil fauna are diverse, abundant, and critical to ecosystem functions. Soil fauna account for almost 25% of living species.^[1] Although they compose a group of organisms that has been ignored historically when it comes to land management, there is growing recognition and understanding of the roles soil fauna play in ecosystems. Appreciation for which organisms are present in soil, their habitats, community diversity, and contributions to ecosystem functions, stability, and sustainability is increasing with accumulating evidence from scientific research. Further development of our understanding of soil ecology is essential because soil fauna contribute directly and indirectly to properties and processes at the scale of the organism and its habitat with outcomes observed up to field and landscape levels. Future research efforts that build on past discoveries should enhance our understanding of how soil fauna connect aboveground and belowground ecology for the proper management and sustainability of ecosystems and ecosystem services.^[2]

SOIL FAUNA—ORGANISMS

Soil fauna, protists, and animals include organisms that span orders of magnitude in size (from micrometer to centimeter to meter). Generally, soil fauna are eukaryotic, aerobic chemoheterotrophs, but they occupy many niches in soil food webs.^[3] Organisms are commonly distributed into groupings that can range from low to high taxonomic resolution. One common differentiation is classification by size. Sized-based groups are microfauna, mesofauna, macrofauna, and megafauna. (See soil microbiology and

ecology textbooks for more detailed descriptions of the groups.^[4–7])

Because categorization based on size is an empirical separation, the upper size cutoff value may differ depending on the reference in the literature that one is searching. Microfauna may be considered up to 100–200 μm in length and include protozoa and nematodes. Nematodes (phylum Nematoda) may also be designated as mesofauna in the literature. Protozoa (kingdom Protista) are often grouped into flagellates, amoeba, and ciliates. Flagellates and amoeba tend to be smaller and numerous, while ciliates are relatively larger and less numerous. Protozoa consume bacteria, protozoa, and other organisms. Abundances range from 10 to 10^5 g^{-1} soil.^[8] (The diverse range of numbers for soil faunal abundances is related to the heterogeneity of soil conditions.) Nematodes, roundworms, are often grouped by into trophic groups: bacterivores, fungivores, omnivores, predators, and plant parasites. Microfauna, and also the mesofauna enchytraeid, are considered to reside in water films and water-filled pores inside aggregates.^[9,10]

Mesofauna range from 100 (or 200) μm to 2000 (sometimes considered up to 10,000) μm . At this larger size range, mesofauna are considered to be in the interaggregate pore space, which is likely to be air-filled, rather than the intra-aggregate pore space expected to be occupied by microfauna.^[11] This category includes micro-arthropods such as springtails (subclass Collembola) and mites (subclass Acari), and the enchytraeid (family Enchytraeidae; potworms). Micro-arthropod abundances may range from 10 to 10^5 m^{-2} (reviewed in Coleman et al.)^[5]. Enchytraeida are particularly important in temperate and boreal forests (reviewed in Huhta et al.)^[12] at abundances ranging from 10^3 m^{-2} to greater than 10^5 m^{-2} . Enchytraeida consume fine plant litter covered in fungi and bacteria. Collembola

are likely omnivorous, although they are often considered fungivorous, and mites feed on fungi, plant detritus, or are predaceous.^[5] Mesofauna are generally regarded as important consumers in litter transformation, especially important given that about 90% of terrestrial organic inputs are processed through detrital food webs.^[5]

Macrofauna are generally considered to be greater than 2 mm, up to a few centimeters, and some species of earthworms are meters long. Macrofauna are often cited as including ants (widely distributed, family Formicidae), earthworms (phylum Annelida; class Oligochaeta), termites (tropical and some temperate; Termitidae in the Order Isoptera), and macro-arthropods (phylum Arthropoda). Earthworm abundances range from less than 10 m⁻² to greater than 1000 m⁻² in temperate and tropical ecosystems.^[13] When present, ants and termites can be so abundant that researchers often do not enumerate abundances. Megafauna sometimes include earthworms and include vertebrates such as moles, gophers, and prairie dogs that can be important in many ecosystems.^[14] Macrofauna and megafauna can be ecosystem engineers. These organisms are too large to exist within the existing pores; in soil, they move soil particles, modify soil pore structure, and create structures such as aggregates.^[15,16] In general, ecosystem engineers modify their physical environment and resources for others.^[14–17] Further, they alter the environment distinctively from abiotic processes.^[14,17]

Much of the biological activity in soil occurs in a small volume relative to whole that poses logistical challenges in representative sampling. However, these “hotspots” or small volumes of soil where conditions are conducive for high activity can be placed in important functional domains.^[16] These domains, or spheres of influence regulating microbial activity, are often associated with the activity of larger organisms, such as plant roots and macrofauna, and include examples such as rhizosphere (zone of influence around a root), drilosphere (zone of influence around an earthworm burrow), and termitosphere (zone of influence under termite activity). Macrofauna create conditions conducive for high rates of activity by directly changing the “architecture” of soil at scales relevant to smaller organisms,^[18] and the accumulation of their direct and indirect activities changes properties and processes in fields. Macrofauna may reside in the surface litter layer (e.g., epigeic earthworms) and soil (e.g., endogeic earthworms) and/or move across soil–litter boundaries (e.g., anecic earthworms). Macrofauna are also involved in important symbiotic relationships in soil, such as protozoan gut communities in termites, fungus gardens of termites, and microbes in the external rumen of earthworms.^[7]

SOIL FAUNA—DIVERSITY AND BIOMASS

The enormous diversity of fauna means that not all groups have been identified and described. Fauna grouped by size

may be placed into broad taxonomic categories that use trophic status for differentiation. Beyond taxonomic classifications, soil fauna are often placed into functional groups. Characterizing communities based on functional groups or higher-level taxonomic groups may provide stronger statistical power^[19] than trying to identify organisms at finer resolution. However, species may feed across trophic levels,^[20] and thus taxonomic trophic groups may not be the most appropriate level of resolution for understanding the functional importance of soil fauna. Salamon et al.,^[21] e.g., found that different species of Collembola respond to increases in fungal compared to bacterial biomass. Although there is one food web aboveground, there are both bacterial-based and fungal-based food webs operating belowground.

Despite the difficulty of determining the appropriate level of resolution to understand soil faunal diversity, diversity is an important consideration for processes, ecosystem functions, and productivity. There is much that is not well known about the diversity of belowground communities. Regardless, it is safe to state that both local and global diversity of soil fauna are huge (reviewed in Coleman).^[3] Estimates for numbers of species can span hundreds in a few hundred square meters.^[22] However, relatively few taxa may dominate soil communities within a land use. In the Southeastern United States, rank–abundance relationships suggest that a few taxa dominated in four land uses, with most abundant taxa belonging to different types of beetles in cultivated and pasture sites, centipedes in hardwood forest, and millipedes in pine stand forest.^[23] A large portion of biomass in tundra, boreal forest, and temperate forest soil (high latitude ecosystems) was accounted for in enchytraeid, while earthworms dominated in tropical forests and temperate grassland soils.^[24] Mites, Collembola, and Enchytraeidae are abundant in acidic forests with thick organic layers.^[20] Despite the diversity of organisms, there are a few predominant organisms in ecosystems in many studies, i.e., many rare, and few cosmopolitan taxa.

A modern survey of soil animals (i.e., not including protozoa) in 11 locations around the globe using molecular analysis of 18S rDNA sequences resulted in a dominance of nematodes and micro-arthropods.^[25] Almost 96% of operational taxonomic units (surrogate for species defined by 99% sequence similarity) were detected in one location only, indicating high endemism and a lack of cosmopolitan species.^[25] Predominance of nematodes (grasslands) and micro-arthropods (forests) was related to pH with nematodes positively correlated and micro-arthropods negatively correlated with pH. In fact, several environmental variables were related to abundances of different groups; micro-arthropods predominate in forests with lower pH, root biomass, mean annual temperature, inorganic nitrogen (N), and higher carbon (C)/N ratio, litter, and moisture.^[25] Further, on a global scale, the soils from ecosystems with higher aboveground plant diversity

had lower belowground faunal diversity.^[25] Diversity matrices have been less informative than multivariate analyses.^[25,26] Thus, it may be that diversity per se is not the best approach to assessing soil faunal communities, whereas multivariate approaches relating abundance and functional structure to environmental variables may be informative.

While it is generally postulated that high biodiversity levels are positive for ecosystem health, stability, and function, there may be much functional redundancy among soil fauna. Impacts of fauna depend in part on characteristics of the ecosystem. In a field experiment investigating the contributions of soil fauna to litter decomposition, fauna of all size classes increased decomposition of litter in its home environment when the plant community was in late succession and contained more recalcitrant compounds.^[27] In early succession, when litter contained easily degraded compounds, the presence of an indigenous community was less important. Often there are changes in taxonomic groups within a system but little change in diversity. Thus, it may be that functional structure of soil fauna is more important than taxonomic structure in ecosystems. Responses to elevated carbon dioxide concentrations were related to trophic structure among soil biota in a meta-analysis.^[28] Abundances of detritivores increased, while there were no changes at higher trophic levels. So, change in the functional characteristics of species composition is important. In a microcosm study, Cole et al.^[29] found that an increasing density of micro-arthropods increased nitrate concentrations but increased richness decreased N mineralization and nitrification. The authors suggest that increased predation pressure with increased richness decreased the microbivore grazing of remaining micro-arthropods. Thus, they concluded it was not a change in richness per se that was important but a change that altered functional group status that was important for functioning.

The study by Cole et al.^[29] also brings to light another question in understanding the impacts of soil fauna on ecosystems. In addition to the extent of diversity, be it functional or taxonomic, among ecosystems, there is also a question of whether total abundance of soil fauna or diversity is more important. In another global meta-analysis of seven biomes, the authors estimated biomass of five major faunal groups. Despite the challenges in computing estimates for biomass that resulted in low to medium confidence for several of the estimates from several biomes, faunal biomass was found to be 40–80% of animal biomass in different biomes except desert.^[24] However, soil faunal biomass (with the exception of deserts at <0.02% of microbial biomass) averaged 2% (1.5–3.6%) of microbial biomass.^[24] Microbial biomass is 2–5% soil organic C, which is usually 1–5% of soil by volume. Despite composing a minor amount of the biomass in soil, soil fauna are major players in many important functions in terrestrial ecosystems.

SOIL FAUNA—ROLES IN ECOSYSTEM FUNCTIONS, STABILITY, AND SUSTAINABILITY

Lavelle et al.^[2] argue that invertebrates are a “resource that needs to be properly managed to enhance ecosystem services” since fauna mediate soil formation, nutrient cycling, primary production, and regulation services. Soil organisms alter soil aggregation through the production of particular compounds, the physical breakdown of organic materials, and the movement of soil particles. Changing soil pore and aggregate structure impacts water infiltration or run-off, and distribution and water storage within the soil profile. Water content affects the habitat, diffusion of gases and compounds, and activity and access of soil organisms, which has implications for the rates and extent of nutrient cycling. Grazing consumes microbes, changes community structure and activity, and releases nutrients. Soil fauna may consume microorganisms, other fauna, and plant detritus. Thus, soil fauna impact nutrient cycling directly through the incorporation and comminution of plant detrital materials and indirectly through the consumption, movement, selection, and activation of microbial communities. These processes impact sequestration of C (and other nutrients) in soil and gaseous releases that affect climate. The activities of soil fauna impact root production and enhanced nutrient cycling can increase aboveground plant biomass.^[30]

While the negative impacts of pests and pathogens are well studied and appreciated because of the economic damage they can cause, the positive impacts of the activities of soil fauna on plant growth and other ecosystem functions are often less appreciated and intentionally utilized. Ingham et al.^[30] demonstrated the positive influence of free-living nematodes on plant biomass by inoculating soil with bacteria and bacterial-feeding nematodes. About 30% N taken up by plants can come from mineralization as a result of grazing of fauna on soil microorganisms.^[31] The presence of earthworms has been shown to decrease plant parasitic nematode infection of rice by more than 80%, allowing plants to maintain biomass production similar to uninfected plants.^[32] In a modern study as part of the biodiversity experiment in Jena, Germany, use of the insecticide chlorpyrifos decreased the biomass of two functional plant groups (forbs and grass), indicating that negative effects from reductions in Collembola abundance, whose grazing of microorganisms contributes to nutrient cycling, outweighed benefits that might have been gained from reductions in herbivore populations.^[33]

Soil fauna are an integral component of belowground ecology that can alter aboveground ecology, but these fauna also respond to aboveground management. Fauna may respond to or emit plant signaling compounds (reviewed in Kardol and Wardle).^[34] Reestablishing mixed forests in coniferous stands changed *Collembola* species richness and diversity, highlighting how aboveground management can affect belowground ecology.^[35] In a study comparing conventional practices to organic wheat farming, organic

management promoted both aboveground and belowground interactions with positive effects on soil fauna compared to a conventional system using mineral fertilizers and herbicides.^[36] Organic management improved soil quality by enhancing generalist predators (top-down control); however, the system was also enhanced through the addition of resources (bottom-up control).^[36]

Subject to much debate is whether terrestrial systems and soil food webs are controlled by bottom-up or top-down forces. Invertebrate numbers and populations respond to or covary with soil properties, such as soil organic matter (OM), temperature, and electrical conductivity.^[26] However, there are conflicting data about which properties and the degree of importance of properties control soil fauna. Mites correlated positively with high soil OM.^[27] Soil pH is an important controlling variable. For example, enchytraeid are abundant in low pH soil.^[20] Soils are often considered to be controlled through bottom-up controls. However, research results do not necessarily clarify the debate. Although microorganisms are the primary agents of decomposition in soil, microbes do not always respond to resource inputs. This may be in part because fauna are consuming biomass, and thus preventing measurable increases in microbial production. In a temperate deciduous forest in Germany, while particular organisms responded to resource input, the structure of the food web was not clearly related to bottom-up control.^[21] Earthworms changed habitat for other organisms, reducing effects of resource inputs.^[21] Increased predation pressure reduces N mineralization, presumably through cascading effects that reduce grazing of microorganisms.^[29,36] These results indicate that top-down control of food web dynamics is also important in understanding how functions emerge in systems. Taken together, there is many gaps in the data for many groups of fauna to adequately assess what conditions lead to the greatest diversity. It is often hypothesized that with little disturbance and much competition, diversity will be limited, and under too much stress, diversity will be limited. However, the heterogeneity of soil, patchy community structures, and the activities of ecosystem engineers may all complicate these relationships and lead to high diversity of fauna in soil ecosystems.^[37]

In addition to diverse community composition, inherent spatial and temporal variability in soil properties and activities and interactions of organisms poses challenges in accurate assessments. In a study investigating the literature from 1940 to 1992, spatial variability of mesofauna and macrofauna was analyzed.^[19] While common species showed lower variation than rare species, the coefficient of variation for common species was often 100% with much of the variability attributed to random error.^[19] An important step in making cross-study comparisons is to standardize field collection methods to assess soil faunal communities.^[38] Abundances and diversity are often greatest at the soil surface. While organisms can be found at

depths below 30 cm, Callaham et al.^[23] discontinued sampling in four land uses in the Southeastern United States at the 15–30 cm depths for their faunal community assessments because fauna were found at the 0–15 cm soil depth. Abundances often need to be transformed to fit parametric statistical analyses. Distributions can be difficult to sample representatively because they are patchy at best within an ecosystem and variable in response to soil properties and to disturbances.^[39,40] Further, distributions and activity are temporally variable. For example, enchytraeid activity is closely related to rainfall.^[41]

Soil fauna are responsive to changes in their environment. This responsiveness, which occurs in part because the soil is their habitat, makes soil fauna useful indicator organisms of disturbance, recovery, and soil quality.^[42] Nematodes, e.g., have been used as indicators of ecosystem recovery and function, maturity, and the soil food web.^[43,44] Earthworms are utilized as indicators of pollution, including heavy metals. However, their diversity in niche separation may make it difficult to interpret responses. We remain limited not only by scale of resolution in sampling and identification but also by what we do not know about the biology and ecology of unidentified and even identified organisms. Barbercheck et al.^[26] suggested separating Collembola by habitat type for effectiveness of using Collembola as indicators. However, relying on one indicator or group of indicators to describe effects of disturbance among ecosystems is not advised.^[19,26]

In restoration ecology, it has been proposed that to restore ecosystems, one must integrate the belowground with the aboveground.^[34] Organisms are useful as indicators because they integrate cumulative effects of chemistry and physics. However, there are different types of disturbances that occur at different frequencies, intensities, durations, and extent of spatial coverage. Greater diversity of fauna was measured in the less disturbed hardwood forest site, followed by the pine stand, followed by pastures, and the least diversity occurred in cultivated soil in four land uses in Southeastern United States.^[23] Native earthworms were present in fields and forests but most commonly collected from forests.^[23] Introduced earthworms were most often collected from cultivated fields and pastures. Introduced species are well known for drastically altering characteristics and functions of ecosystems, especially if they become invasive. The introduction of non-native earthworms has resulted in change in the location and cycling of OM in forests, such that ecosystems are no longer sustainable (northern U.S. forests).^[45] It is frequently expected that introduced organisms will be more common in disturbed areas and native species more common in undisturbed locales.^[46] However, although reduced in abundance, native species are not always eliminated from an ecosystem as a result of a disturbance. To what extent native and introduced organisms co-occur and alter ecosystem function needs research.

CONCLUSION

Although there is growing recognition of their integral effects on soil functions, soil fauna have been largely ignored in the development of land management plans. There is an accumulating body of knowledge of the importance of these organisms in driving ecosystem functions. Beyond the small size of many organisms, soil fauna may not have received deserved levels of research attention because there is general agreement that most important drivers of nutrient cycling are microorganisms. However, soil fauna interact with microbes, influence community structure and dispersal, change the physical environment, and facilitate decomposition and nutrient cycling. Soil fauna may be the link that is necessary to connect microorganisms to fields and landscapes, i.e., the scale at which processes are observed.

Fauna and Microflora: Macrofauna

Judy Tisdall

Department of Agricultural Sciences, LaTrobe University, Bundoora,
Victoria, Australia

Abstract

This entry discusses earthworms, termites, and ants and their effect on soil structure. One or more of these groups generally dominate the soil fauna.

INTRODUCTION

Soil macrofauna (>2 mm) live all or part of their life below ground (Table 1). Through turnover (or bioturbation) of soil, the macrofauna contribute significantly to the structure, texture, and nutrient cycling of soil. Tillage destroys macrofauna habitat and food, hence the number of macrofauna is usually higher in undisturbed soils than in tilled soils.

EARTHWORMS

About 3000 species in 20 families of earthworms have been identified, and their distribution and number of species vary with climate and soil management. Earthworms affect soil structure by producing casts and burrows.

Casts

Earthworms daily ingest and mix in the gut about half their own mass of soil plus large volumes of organic matter and deposit the material as casts. Each year, earthworms deposit 0.3–27.0 kg m⁻² of casts on the surface of the soil, with more below the surface.^[1] Earthworms remould the soil in the gut^[2] so that fresh casts can be up to 15% more dispersive, i.e., less stable,^[3] than the surrounding soil and can easily be eroded during rain. As they age and dry, the casts often become more stable and stronger than the surrounding soil, due to age hardening, cohesive forces of water and cements, clay-bound carbohydrates, and microorganisms.^[4–6] By preventing the formation of crusts, stable casts on the surface of soil often increase infiltration and seedling emergence. Physical properties of casts may depend on the properties (content of clay, water or organic matter, or compaction) of the original soil.^[2,3,7] Some casts produced in very wet soil are so dense and hard that the movement of water and air, mineralization of carbon, and root growth is decreased.^[4,8]

Burrows

The main types of burrows are as follows: 1) semipermanent vertical burrows from the surface to at least 3 m depth; 2) almost horizontal and some vertical burrows to the surface; and 3) deep temporary burrows.^[1] Extensive networks of horizontal and vertical burrows develop in soils with several species of earthworms, but may vary seasonally, being filled with casts or destroyed by tillage or mammals.^[9]

Earthworms can produce burrows in soil at least as hard as 3 MPa, whereas roots are often limited in soil at 2 MPa.^[10] Many burrows are stable and may persist long after the earthworms have left, possibly because the burrows are lined with orientated clay or humic materials, carbonates and iron oxides.^[1] The burrows can be up to at least 10 mm wide depending on the size of the earthworm. The burrows affect the continuity and tortuosity of pores and often increase the macroporosity and infiltration in the soil.^[9] The matrix of the soil may be wetted laterally from open burrows rather than from the surface of the soil.^[11] Water that is absorbed into the matrix may later move back to burrows. Although water runs down the burrows during rainfall in temperate climates, the burrows always contain air and do not need to be linked for better aeration of the matrix.^[9]

Roots can grow along the earthworm burrows,^[12] possibly through hard, dry, waterlogged, or acidic soil to reach nutrients and water in soft, moist, drained, or neutral soil. However, water, nutrients, and pesticides may follow burrows below the root zone and pollute the groundwater.^[4]

TERMITES

Termites consist of several thousand species, with several castes in a colony.^[13] Termites turn over 0.02–470 t soil ha⁻¹ yr⁻¹, affecting over 0.5–20% of the soil surface.^[14] Termites can increase erosion by removing protective litter from the surface and bringing dispersive particles to the surface.

Table 1 Climatic zone, feeding habit and food of invertebrate macrofauna in soil.

Fauna		Climatic zone	Feeding habit (food)
Oligochaeta			
Earthworms		All but driest and coldest	Saprovores, geovores (organic litter, soil)
Macroarthropods			
Isopods		Various including desert	Saprovores, predators (organic litter, roots and leaves of seedlings)
Millipedes (Diplopoda)		Temperate, tropical, arid, semiarid	Saprovores (leaf litter, dung)
Centipedes (Chilopoda)		Forest to desert	Saprovores, predators
Scorpions		Mainly desert; also warm dry tropics, temperate	Predators, cannibals
Spiders (Araneae)		All but Arctic/Antarctic	Carnivores, predators (arthropods, small vertebrates)
Termites (Isoptera)		Mainly tropics, subtropics; also temperate and deserts	Saprovores (wood, plants, lichens, humus, fungi)
Ants (Hymenoptera)		Arctic to tropics	Saprovores, carnivores, predators (organic litter, seeds, secretions of plants and aphids, plants)
Wasps (Hymenoptera)		Temperate, tropics	Saprovores (nectar, sap)
Beetles (Coleoptera)		Temperate	Saprovores, predators, carnivores (dung, animal carcasses, seeds, roots)

Termites build a wide range of nests (mounds), in which they live and store food, and sometimes runways and subterranean galleries (i.e., the nests contain large pores). The nests and runways consist of soil, excreta, plant residues, and sometimes saliva, often with higher concentrations of clay, exchangeable cations and microbial activity, than the surrounding soil.^[14,15]

Mounds are usually up to at least 30 cm wide and 9 m high,^[13,14] with 200–1000 small mounds ha⁻¹, or 2–10 large mounds ha⁻¹; there are few mounds on sands, self-mulching clays, and shallow soils. Mounds last from 8 to 80 years, surviving while the mound is active. Once inactive, mounds are quickly eroded, especially when dug by mammals.^[13] The surface becomes covered with fine particles of subsoil, adding 25–1000 mm depth of soil every 1000 years. The runways are quickly eroded by rain and rebuilt just as quickly.

The few reports available suggest that termites have less overall effect on soil structure than do earthworms. Some termites slightly increase the bulk density of soil, probably because they repack the soil particles and select fine particles. Reports on the infiltration of water in termite galleries differ from that of the surrounding soil, although water-holding capacity is usually higher in the mounds.^[14]

ANTS

There are at least 15,000 species of ants, all of which are social insects living in colonies with up to 500,000 individuals, with a biomass of 0.1–0.8 g m⁻².^[14] Many ants burrow extensively, producing nests ranging from simple excavations on the surface or under stones to craters and domes.^[16] The mounds are either Type I, which are small and ephemeral, or Type II, which are large and dense and

can last for more than 100 years.^[17] Ants move between 3–11,360 kg of soil ha⁻¹ yr⁻¹ (agricultural land) and 21–8410 kg ha⁻¹ yr⁻¹ (natural vegetation) depending on the species.^[18] Ants mix soil and litter, or decompose organic litter or the surface of soil, deposit subsoil on the surface,^[19] and appear eventually to homogenize the texture to a depth of at least 260 mm.^[20]

The effect of ants on soil structure has not been greatly studied. However, compared with the surrounding soil, the mounds may have a lower plastic limit,^[19] be more stable and denser^[14] (at least at the top of the mound), or less dense,^[19,21] with higher macroporosity due to the galleries.^[22] The infiltration rate into an ant nest was over three times that of the surrounding soil,^[14] probably through the galleries. Compared with the surrounding soil, infiltration into ant mounds was increased as the liquid moved to a depth of 2 m through vertical and lateral galleries.^[22] However, ants expose bare soil around their burrows, which could impede infiltration and encourage soil erosion.

Fertility Decline: Definitions and Assessment

Alfred E. Hartemink

International Soil Reference and Information Centre (ISRIC), Wageningen, the Netherlands

Abstract

Assessing soil fertility decline is difficult because most soil chemical properties either change very slowly or have large seasonal fluctuations; in both cases, it requires long-term research commitment. There are several other confounding factors that make the assessment of soil fertility decline complicated (e.g., spatial and temporal variation and soil analytical methods) and, for those reasons, other techniques have been used to estimate the rates and changes in soil fertility decline. The methods to assess soil fertility decline are described in this entry.

INTRODUCTION

In permanent agricultural systems, soil fertility is maintained through applications of manure, other organic materials, inorganic fertilizers, lime, the inclusion of legumes in the cropping systems, or a combination of these. In many parts of the world, the availability, use, and profitability of inorganic fertilizers have been low whereas there has been an intensification of land use and an expansion of crop cultivation onto marginal soils. As a result, soil fertility has declined and it is perceived to be widespread, particularly in sub-Saharan Africa.^[1–3] Soil fertility decline is considered as an important cause for low productivity of many soils.^[4,5] It has not received the same amount of research attention as soil erosion; possibly as soil fertility decline is less visible and less spectacular and more difficult to assess.

DEFINITIONS

Growing agricultural crops implies that nutrients (nitrogen, phosphorous, potassium, etc.) are removed from the soil through the agricultural produce (food, fiber, and wood) and crop residues. Nutrient removal may result in a decline of the soil fertility, if replenishment with inorganic or organic nutrient inputs is inadequate. Soil fertility is defined as “the quality of a soil that enables it to provide nutrients in adequate amounts and in proper balance for the growth of specified plants or crops.”^[6]

Although it omits the importance of soil physical and biological conditions for crop productivity, it is a useful simplification. A decline in soil fertility implies a decline in the quality of the soil, and soil fertility decline is defined as “the decline in chemical soil fertility, or a decrease in the levels of soil organic matter, pH, cation exchange capacity (CEC), and plant nutrients.”

Soil fertility decline thus includes:

1. Nutrient depletion or nutrient decline (larger removal than addition of nutrients).
2. Nutrient mining (large removal of nutrients and no inputs).
3. Acidification (decline in pH and/or an increase in exchangeable Al).
4. The loss of organic matter.
5. An increase in toxic elements (e.g., aluminum and magnesium).

ASSESSMENT OF SOIL FERTILITY DECLINE

Different data types are used to assess soil fertility changes: 1) expert knowledge; 2) monitoring of soil chemical properties over time or at different sites; and 3) nutrient balances. Some of these data can be relatively easily collected, whereas some other data require long-term commitment and involve high cost. Each data type has specific advantages and disadvantages, and the type of data collected is determined by the research plan, the financial conditions, and objectives of the study (Table 1).

Expert Knowledge

Farmers and other users of the land have expert knowledge about their soils; this is mostly empirical knowledge, which is not soil process or data oriented, but yield or management oriented.^[7] Yield decline as observed by a farmer could, however, be caused by a variety of factors including soil fertility decline, adverse weather conditions, invasion of weeds, soil physical deterioration, or a combination of factors. It is difficult to distinguish soil fertility decline from other factors,

Table 1 Data types in soil fertility decline studies and their advantages and disadvantages.

Data type	Short description	Advantages	Disadvantages
Expert knowledge	Combination of field observations with general knowledge	Easy to obtain, rapid assessment, useful for small-scale studies	Subjective, not quantitative
Measured values Type I Chronosequential	Monitoring soil properties over time	Accurate, hard data, using existing data	Slow, expensive, contamination of monitoring sites, spatial and temporal variability, sample storage
Measured values Type II Biosequential	Comparing soil properties under different land use	Easy to obtain, rapid, relatively hard	Soils at sampling sites may differ, unknown land use history of sites, spatial and temporal variability
Nutrient balances and budgets	Combination of existing data with pedotransfer functions or models	Using existing data, fairly rapid, indicative, appealing outcome	Not very hard, require computer power

Source: From Lal.^[4]

and farmers' knowledge on soil fertility decline must be substantiated by other types of data, e.g., crop yield, weather conditions or pests, and disease information. Farmers' knowledge can be instrumental in selection of sampling sites or for additional information and various examples in the literature exist where such information was used to investigate long-term changes in soil fertility.^[8,9] Another form of expert knowledge is that of soil scientists and agronomists who can make some estimation on the soil fertility status and its changes based on vegetation or crop growth. As with farmers' knowledge, such information is important but not very quantitative.

MEASURED CHANGE IN SOIL CHEMICAL PROPERTIES

Two different approaches have been used to monitor soil chemical properties. First, soil dynamics can be monitored over time at the same site, which is called chronosequential sampling^[10] or Type I data.^[11] Type I data show changes in a soil chemical property under a particular type of land use over time. Usually the original level is taken as the reference level to investigate the trend in such changes. It is most useful if trends are also followed under other land use systems, e.g., under cultivation, secondary regrowth, and natural forest over the same period. Type I data have been used for quantifying soil contamination by comparing soil samples collected before the intensive industrialization period with samples taken from the same locations.^[12] Type I data are also useful to assess the sustainability of land management practices in the tropics,^[13] but limited data sets exist as they require long-term research commitment and detailed recordings of soil management and crop husbandry practices.^[14]

In the second approach, soils under adjacent different land use systems are sampled at the same time and

compared. This is called biosequential sampling,^[10] Type II data,^[11] "sampling from paired sites" in the soil science literature from Australia,^[15,16] the "space-for-time" method,^[17] and the "inferential method."^[18] The underlying assumption is that the soils of the cultivated and uncultivated land are the same soil series, but that differences in soil properties can be attributed to the differences in land use. Obviously, this is not always the case and the uncultivated land may have been of inferior quality and therefore not planted. Also, spatial variability may be confounded with changes over time when, e.g., tree crops of different age are sampled at the same time, and soil properties are often confounded with genetic improvement and silvicultural practices.^[11] Other confounding factors are differences in clay content, soil depth, or unknown history of land use, and these largely affect the usefulness of Type II data for the assessment of soil fertility decline. In ecology, Type II data studies have often proved to be misleading as functional parameters like nutrient availability and plant-animal interactions have been conspicuously underrepresented.^[17] When carefully taken, however, biosequential soil samples can provide useful information, and this sampling strategy has been followed in a considerable number of studies.^[14]

Monitoring of soil chemical properties gives information on how soils respond to agricultural activities and whether soil fertility decline takes place. Spatial and temporal variation requires a cautious selection of sampling sites, an appropriate number of replicated observations, and a careful interpretation of the results. Provided these are met, it may be difficult to extrapolate the information or to derive maps of the patterns observed in single pedons. Coupling the soil information to soil maps in a geographical information system (GIS) provides opportunities to map soil fertility decline in different areas. A large amount of data of sufficient quality is needed before such maps can be derived, and there are few examples where measured soil fertility decline was

coupled to a GIS.^[19] More studies exist in which the nutrient balance has been used to map soil fertility decline.

Nutrient Budgets and Balances

A third way of studying soil fertility decline embraces a semiquantitative approach using partial nutrient balances and budgets. Such studies operate at a much coarser (smaller) scale, namely, national or supranational scale, and available soil data are combined with pedotransfer functions (regression analysis between some soil or other parameters) into a GIS to estimate the decline in soil fertility at a given location.^[20] This is essentially a mechanistic modeling approach in which expert knowledge is also important. It is generally perceived that such studies are not to replace soil-monitoring efforts but must be seen as the best possible way of getting the most out of available data.^[14] The outcome of such studies provides qualitative, comparative, and spatial information on the decline in soil fertility.

Nutrient balances provide a convenient and biologically meaningful context within which to organize what is known about a system's biogeochemical cycles, put nutrient pools and fluxes into perspective, and can lead to considerable insight into processes that regulate nutrient cycling. Nutrient balances help to guide system management decisions and direct the course of future research.^[21] The use of nutrient balances has been encouraged through a systems approach to both improve food crop production and maintain the soil resource base.^[22]

CONCLUSION

Evaluating soil fertility decline can be done with different types of data. There are data from measured soil chemical properties, and such data can be from the same plot that is permanently cultivated (Type I data) or from plots under different land use (Type II data). Soil fertility decline can also be assessed in a more semiquantitative way using nutrient balances. Each data type has its merits and drawbacks, and data are either quickly collected and indicative for what is going on or the collection is more tedious which usually implies that the data are harder and more meaningful. Boundary conditions need to be properly set and the study must indicate whether soil fertility decline is assessed for a pedon, watershed, region, country, etc. At the watershed level, soil fertility may decline in one pedon but it may increase in a lower pedon, which illustrates the need for the delineation of spatial boundaries. Soil fertility decline studies must also have temporal boundaries and in general long-term observations yield better results.

An important aspect in soil fertility decline studies is the spatial and temporal variation in soil properties. Soil

spatial variation has been sufficiently tackled by research and various methods exist to quantify the variation. Temporal variation is a more difficult issue, and fewer studies are available. As with spatial variation, it requires a sufficient amount of subsamples and samples before rigid conclusions can be drawn. Soil fertility decline studies are largely dependent on soil chemical analysis, which include soil sampling, soil analysis, and interpretation of the results. Errors are possible in all three steps, although most errors are generally being made during soil sampling. The choice of the analytical technique in relation to the soil property or soil type is another potential source of errors.

Fertility: Environmentally Compatible Management

Bal Ram Singh

Department of Environmental Sciences, Norwegian University of Life Sciences, Aas, Norway

Abstract

Soil fertility integrates the basic principles of soil biology, chemistry, and physics to develop the practices needed to manage nutrients in a profitable and environmentally sound manner. Maintenance and management of soil fertility is central to the development of sustainable food production systems. Sustainability is dependent to a large degree on recycling the inputs into a production system, thereby increasing efficiency of output per unit of resource input. The essential plant nutrients may be divided into macronutrients (nitrogen, phosphorus, sulfur, potassium, magnesium, and calcium), micronutrients (iron, manganese, zinc, copper, boron, molybdenum, chlorine, and nickel), and beneficial elements (sodium, silicon, and cobalt). The modern soil fertility management in addition to involving soil productivity must also include the protection of the environment, and, therefore, issues related to soil quality, water quality, air quality, heavy metals, food quality, and safety are discussed. Nutrient mining and loss of organic matter lead to deterioration of soil quality and accelerated eutrophication of surface waters and nitrate content of drinking water are the main concerns for water quality. The nitrous oxide produced during nitrification and denitrification contributes to global warming and stratospheric ozone depletion and thus poses threats to air quality. Anthropogenic inputs of metals through fertilizers, amendments, sewage sludge, pesticides, mining, and industry lead to soil contamination, creating concern for food safety. A number of management practices to reduce metal transfer to food chain are tested with varying success.

INTRODUCTION

Soil Fertility in the Past

In writings, dating back to 2500 B.C., the fertility of land is mentioned. Herodotus, the Greek historian, traveling through Mesopotamia some 2000 years later reported the phenomenal yields obtained by the inhabitants of this land. Later Theophrastus (372–287 B.C.) recommended the abundant manuring of thin soils but suggested that rich soils be manured sparingly. During the 17th and 18th centuries, agricultural writings reflected that plants consisted of one substance, and most of the workers were searching for this principle of vegetation during this period. It was not until the latter half of 19th and the beginning of the 20th century that some progress was made to understand the subject of plant nutrition and crop fertilization. It was Justus von Liebig (1803–1873), a German chemist, who effectively deposed the humus myth and eventually developed the law of minimum. The law says that the growth of plants is limited by the plant–nutrient element present in the smallest quantity, all others being present in adequate amounts. These developments led to a rapid increase in chemical fertilizer's use.

Soil Fertility in Modern Times

With advances in our knowledge with regard to various processes affecting the nutrient dynamics in soils, the

definition of soil fertility is also refined. Soil fertility integrates the basic principles of soil biology, chemistry, and physics to develop the practices needed to manage nutrients in a profitable and environmentally sound manner. The focus of soil fertility is to manage nutrient status in soils to create optimum conditions for plant growth. Two fundamental principles underlay the study of soil fertility. First is the recognition that optimum nutrient status alone will not ensure soil productivity. Other factors, such as soil moisture and temperature, soil physical conditions, soil acidity and salinity, and biotic stress, can reduce the productivity of even more fertile soils. Second is the realization that modern soil fertility practice must stress soil productivity and environmental protection.^[1] Taking the second realization in perspective, it is imperative that soil fertility in relation to agricultural sustainability and environmental protection will be the focus of this entry.

SOIL FERTILITY AND AGRICULTURAL SUSTAINABILITY

A new dimension to soil fertility in relation to agricultural production has been added. It is the concept of “sustainability,” which has been defined and interpreted differently by different workers. Okigbo^[2] after analyzing the various definitions of sustainable agriculture by different workers defined “a sustainable agricultural production system as one that maintains an acceptable and increasing level of

productivity that satisfies prevailing needs and is continuously adapted to meet the future needs for increasing the carrying capacity of the resource base and other worthwhile human needs.”^[2]

The sustainability of a production system is location specific and is determined to a greater degree by an interaction among several production factors, namely, physiochemical (soil, climate, radiation, etc.), biological (crop species, weeds and pests, etc.), management, and socioeconomic elements. Maintenance and management of soil fertility is central to the development of sustainable food production systems. Sustainability is dependent to a large degree on recycling the inputs into a production system, thereby increasing the efficiency of output per unit of resource input. Soil fertility management is concerned with the essential plant nutrients, their amounts, availability to crop plants, chemical reactions in soil, loss mechanisms, processes making them unavailable or less available to crop plants, and ways and means of replenishing them in these soils.^[3]

ESSENTIAL NUTRIENTS

Because soil fertility involves management of nutrients required for plant production, it is important to describe briefly the elements, which are considered essential for plant growth. The essential nutrients required by higher plant are exclusively of inorganic nature, and Arnon and Stout^[4] proposed the term essential nutrient (element). The essential element must meet three criteria to be considered essential: 1) a given plant must be unable to complete its life cycle without the presence of the mineral element in question; 2) the function of the element cannot be replaced by another element; and 3) the element is directly involved in the nutrition of the plant—for example, as a component of an essential plant constituent such as enzyme—or must be required for a distinct metabolic step such as an enzyme reaction.

Some elements, which either compensate for the toxic effect of other elements or simply replace mineral elements in some of their less specific functions, such as maintenance of osmotic pressure, can be described as beneficial elements. Out of a large number of elements found in plants, 14 mineral elements are recognized as essential, whereas the requirement of chlorine (Cl) and nickel (Ni) is restricted to a limited number of plant species. The plant nutrients may be divided into: 1) macronutrients [nitrogen (N), phosphorus (P), sulfur (S), potassium (K), magnesium (Mg), and calcium (Ca)]; 2) micronutrients [iron (Fe), manganese (Mn), zinc (Zn), copper (Cu), boron (B), molybdenum (Mo), Cl, and Ni]; and 3) beneficial elements (sodium (Na), silicon (Si), and cobalt (Co)]. The last three elements have been found essential only for some plant species, for example, Na for plants with C4 photosynthetic pathway, Si for rice, and Co for fixation of atmospheric N by rhizobia

and blue green algae, but they have not been included in the list of essential nutrients.^[3]

MANAGEMENT OF SOIL FERTILITY AND THE ENVIRONMENT

As pointed out by Sims^[1] that modern soil fertility in addition to involving soil productivity must also include protection of the environment, and, thus, the environmental aspects related to soil fertility are described under this section. Long-term use of organic and inorganic fertilizers to agricultural soils has led to slow build up of nutrient reserves, especially under temperate conditions. The same nutrients, which are considered essential for plant growth and crop production, if lost from the system, can create a concern for the environment. Increased use of fertilizers for meeting the world food demand and recycling of on-farm organic wastes (manures and slurries) and off-farm organic wastes (municipal and industrial sludges) on agricultural lands in the past decades has resulted in some undesirable effects on the environment in intensively cultivated areas. This has created greater awareness on environmental issues not only among scientists and policy makers but also among general public. Although there are a number of issues related to soil fertility and the environment, emphasis is placed on four main concerns of environmental protection, namely, soil quality, water quality, air quality, heavy metals, and food concerns.

Soil Quality

The export of agricultural produce takes with it large amounts of nutrients (especially N, P, K, and S), and if these nutrients are not replenished, the soil organic matter (SOM) and the fertility of the soil will decline, and the soil will degrade. A number of such examples from the subsistence farming of the tropics are available, where “nutrient mining” of soils has been responsible for decline in soil fertility and soil quality leading to loss of productivity.^[5] The rapid loss of SOM of the topsoil after clearing of the natural vegetation or under continuous cultivation is a common phenomenon in Africa. In Zambia, it was found that the SOM content dropped from 59 to 32 Mg ha⁻¹ after 17 years of cultivation of a newly cleared land, which represented an average loss of 1.6 Mg ha⁻¹ yr⁻¹.^[6]

On the other hand, long-term studies carried out in temperate regions have shown that organic matter of soil can be maintained or raised modestly by proper fertilization, especially by organic manures and crop residue management.^[7] Any management practice that results in an increase in the crop residues returning to soil will have a positive influence on SOM,^[7] which, in turn, will affect soil aggregation and related properties such as soil structure, erodibility, workability, and water infiltration. Growing of legumes is

an effective way for promoting good soil aggregation and for reversing degradative trends.

Water Quality

The major concerns with regard to water quality are accelerated eutrophication of surface waters and nitrate (NO_3) content of drinking water. Eutrophication, the rapid growth and decay of aquatic vegetation, is most often limited by P and sometimes by N concentration in water. A NO_3 concentration of 10 mg L^{-1} in drinking water is considered safe, but higher concentration can cause methaemoglobinaemia (reduced carrying capacity of blood for oxygen) in children.

Both overfertilization and underfertilization can lead to N losses. Losses occur either as runoff to surface water or as leaching to underground waters. Under normal conditions, runoff losses in watersheds are low (e.g., 10 mg L^{-1}). Much of the N transported in runoff is particulate N associated with the sediments, and it can range from 0 to 7 kg N ha^{-1} .^[8] These losses can be reduced by incorporation of fertilizer and providing a good vegetation cover. Much of N losses occur through leaching, but there is a large variation in the quantities of N lost in leaching depending on the amount of N fertilizer applied, soil type, crop grown, and climatic conditions. Letey et al.^[9] reviewed NO_3 concentration in tile effluents from 55 sites of California; the concentration ranged from 1 mg L^{-1} to 196 mg L^{-1} , with only one-quarter of the sites averaging $<10 \text{ mg L}^{-1}$. High nitrate levels in drinking water have also been observed where animal or poultry manures are applied. In Sussex county, Delaware, it was found that 32% of the water wells had high ($>10 \text{ mg L}^{-1}$) nitrate levels.^[10,11]

From surface water viewpoint, P is the element of primary concern, because it is considered limiting for eutrophication. Excessive application of organic and inorganic fertilizers can result in building of P near the soil surface, which is subjected to soil erosion leading to P losses to surface waters. In aquatic ecosystems of southwestern Australia, an excess of nutrients has caused serious eutrophication, which was manifested by excessive growth and accumulation of green and blue green algae.^[12] P is generally the limiting nutrient for algae growth, and phosphatic fertilizers applied to nutrient deficient, leaching, and sandy soils were the main source of P in these ecosystems of Australia.

Air Quality

The primary goal of good nutrient management and especially N should be to maximize N uptake at critical growth stages and to minimize transformation processes, which lead to the formation of "greenhouse gases." The main N-containing greenhouse gas is nitrous oxide (N_2O). The N_2O produced during nitrification and denitrification

contributes to global warming and stratospheric ozone depletion. Annual losses of N as N_2O from fertilized field soil can be as high as 40 kg h^{-1} compared to $<2 \text{ kg h}^{-1}$ from unfertilized soils.^[13] Based on a summary of 104 field experiments conducted in temperate climate, it was reported that almost all experiments showed evidence of fertilizer derived N_2O emissions.^[14] Legumes, such as fertilizers, have been shown to contribute to increased N_2O emissions^[7] caused by enhanced denitrification due to the addition of easily decomposable organic matter. On the other hand, it was found that gaseous losses via denitrification and N_2O emissions from irrigated corn in Shelton, Nebraska, United States, represented only 1–5% of the N applied as fertilizer, and, thus, it was concluded that under good irrigation and good N management practices gaseous N losses from denitrification and N_2O emissions do not pose additional threat to air quality.^[15]

Under tropical climate, N loss to air takes place both through denitrification and volatilization of ammonia (NH_3). High losses of NH_3 in rice fields have been attributed to high concentration of ammonium-N following urea application, high pH, high temperature, and high wind speed. NH_3 loss of applied urea-N ranged from 7% to 54% in Philippines and the loss depended on time and the method of urea-N application. For example, the incorporation of urea before transplanting with no standing water reduced urea-N loss as NH_3 from 42% to 11% at IRRI, Philippines.^[16] Direct field measurement of denitrification has been made difficult by the lack of suitable methodology. Buresh and Austin^[17] used a floating chamber technique to directly collect $(\text{N}_2 + \text{N}_2\text{O})^{-15}\text{N}$ from labeled urea applied to flooded soil and found that the total N loss as unaccounted for ^{15}N by the ^{15}N balance study ranged from 26% to 46% of the applied N.

HEAVY METALS AND FOOD CONCERNS

Contamination Sources

The major sources of anthropogenic inputs of metals to soils are either primary sources as fertilizers and amendments (e.g., lime), sewage sludge, and pesticides or secondary source, where metals are added to the soil as a result of nearby activities such as mining or industry or Aerosol deposition from more distant sources. However, there are also rural areas, where the content of metal in soils is many fold higher due to natural processes and geological formation of soils. A good example is alum shale soils (developed from sulfide-bearing rocks formed in anoxic environment) in southeastern Norway.^[18]

It is well documented that the use of commercial P fertilizers is one of the main sources of metals and especially of cadmium (Cd) addition to agricultural soils.^[19–21]

Besides fertilizers, certain animal waste products may also contain high amount of metals. Pig manure contained

more than twice the amount of Zn (158 mg/kg) and Cu (15 mg/kg) than cow manure because of supplementation of these metals in their diets.^[22] Disposal of biosolids (e.g., sewage sludge) is a potential source to contaminate soils. In many developed countries, soil metal loading through sewage sludge is regulated through “maximum permitted concentration (MPC).”

Soil Contamination with Metals and Guidelines for Soil Quality

That long-term use of fertilizers can lead to increased content of metals in soils is well documented,^[21,23,24] and especially Cd enrichment of soils after long-term use of P fertilizers is reported in many countries.^[20,23,25,26] Many studies based on long-term fertility experiments in United States and Western Europe have shown a net accumulation of Cd in soils.^[20,25,26] The balance calculations based on 70 years data indicated that Cd accumulation in the soil was $<1 \text{ g Cd ha}^{-1} \text{ yr}^{-1}$ but increasing the doses of commercial fertilizers or farm yard manure would likely result in increased accumulation of this element.^[20] In some countries, guidelines to protect soil quality have been developed. A best example of such values is found in The Netherlands. They have developed “reference or target values,” which represent soils with negligible risks and “intervention values,” which represent soils with the maximum possible risk levels (Table 1). In Australia and New Zealand, the environmental soil quality guidelines to protect plant production, animal health, and food quality have been prepared. These soil quality guidelines for Cd, Cu, Pb, Ni, and Zn are 3, 60, 300, 60, and 200 mg/kg, respectively.^[21]

Phytouptake and Phytotoxicity

Soil conditions related directly or indirectly to soil fertility such as soil pH, organic matter and clay content, metal content, moisture content, and soil aeration are determining factors for metal uptake. For these reasons, some workers have found increased plant uptake of Cd added through commercial fertilizers,^[19,24,26,27] whereas others did not

Table 1 Dutch reference values and interventional values (mg kg^{-1}) in soils based on ecotoxicity and human health.

Metal	Reference value for standard soil ^a	Ecotoxicity intervention value	Human health intervention value
Cd	0.8	12	680
Cu	36	190	16,000
Pb	85	290	300
Ni	35	210	6,600
Zn	140	720	56,000

^aStandard soil with 25% clay and 10% organic matter.

Table 2 Cd concentration (mg kg^{-1}) in different crop species as affected by varying levels of Cd in P fertilizer applied.

Cd applied in fertilizer ($\mu\text{g kg}^{-1}$)	Oat grain	Ryegrass	Carrot root	Spinach
0.0	0.06	0.21	0.14	—
2.7	0.07	0.21	0.15	1.52
12.5	0.07	0.24	0.18	1.80

Source: From He & Singh.^[23] ©1993.

find any increase.^[25] The application of P fertilizer containing increasing amount of Cd resulted in increased concentration of Cd in different crops, but the magnitude of Cd uptake differed considerably among crops. For example, spinach contained almost 25 times more Cd than oat grain (Table 2).^[27] Furthermore, increasing disposal of sludges and other organic wastes to agricultural lands has also resulted in increased uptake of metal in plants.^[28,29]

The uptake of Zn, Cu, and Cd in field pea increased significantly in sludge or pig manure treated plots, but liming of these plots reduced the concentration of all metals significantly (Table 3).^[29]

Metals in Foods and Their Regulations

Among the metals, Cd in food stuff is considered a greater risk and hence regulatory limits for food, the so-called “MPC,” have been worked out in several countries (e.g., The Netherlands, Germany, Denmark, Sweden, Australia, and New Zealand). These values do not pose health risks, but they are taken as target concentrations for initiating corrective measures to minimize Cd entry into the food chain. Cd concentration in leafy vegetable is much higher than seed grains and fruits (Table 3). For metals such as lead and mercury, their entry through roots is rather restricted, resulting in their low concentration in food crops.

Table 3 Zn, Cu, and Cd concentration in field pea (*Pisum arvense*) in sludge and pig manure treated soils with and without liming.

Treatment	Zn (mg/kg)	Cu (mg/kg)	Cd ($\mu\text{g/kg}$)
Unlimed			
Control	73.3cd	9.2c	63.2d
Sludge	77.9bc	7.8d	81.8dc
Pig manure	75.3cd	7.4bd	60.9d
Limed			
Control	49.5e	7.0be	37.3e
Sludge	67.5	7.1b	36.7e
Pig manure	61.1f	7.0be	33.5e

Management Practices for Minimizing Metal Transfer to Food Crops

Elevated levels of metals in soils and food crops have created a need to search for management practices, which can reduce metal transfer from soils to food crops. A number of practices have been tested with varying rates of success. However, the mechanisms involved are far from fully understood. One practice, which has been more often used, is liming, but the results obtained have shown both decrease and increase in metal uptake and especially that of Cd.^[27,30] Liming raises soil pH and thus reduces metal concentration in soil, but it also raises the Ca concentration in soil solution. Increased concentration of Ca further complicates the effect of liming. The addition of Zn is shown to reduce Cd uptake by crops and especially under Zn deficiency conditions,^[31] but the mechanism is not known. In metal-rich alum shale soils, increasing rates of cow and pig manures decreased the exchangeable fractions of Cd and Ni.^[22] Other practices, such as crop rotation showed marked effect, where wheat grown after lupins had higher concentration of Cd than wheat grown after a cereal crop.^[32]

CONCLUSION

Soil fertility management is essential for sustainable development of food production systems through recycling of the inputs, thereby increasing resource input efficiency. All essential elements, although very important for plant growth and productivity, can lead to soil contamination and deterioration of water and air quality if applied in excessive and imbalanced ratio. Increased use of fertilizers for meeting the world food demand and recycling of on-farm (manures and slurries) and off-farm organic wastes (municipal and industrial sludge) on agricultural lands in the past decades has resulted in some undesirable effects on the environment in intensively cultivated areas.

Many agronomic management practices have been tested to reduce the undesirable consequences of poor soil fertility management with varying degree of success. However, the mechanisms involved are far from fully understood. Research is needed to explore the ways to reduce nutrient losses to the environment while sustaining soil fertility and improving the food quality with respect to nutritive values and avoidance of harmful elements (toxic metals such as Cd).

Fertility: Evaluation Systems

Ram C. Dalal

A. Subba Rao

Indian Institute of Soil Science, Bhopal, India

Abstract

The soil fertility evaluation is aimed at providing an adequate supply of essential plant nutrients to ensure optimum plant productivity while maximizing economic benefits and minimizing environmental degradation. The essential plant nutrients include nitrogen, phosphorus, potassium, sulfur, calcium, magnesium, sodium, copper, zinc, manganese, iron, molybdenum, boron, and chloride. The soil fertility evaluation systems include biological assessment, plant nutrient analysis, soil testing (chemical, biological, and physical), and spectral sensing for site-specific soil fertility.

BIOLOGICAL ASSESSMENT

The significance of the supply of an essential plant nutrient for crop production was contained in the Liebig's law of the minimum,^[1] which states that by the deficiency or absence of one necessary constituent, all others being present, the soil is rendered barren for all those crops to the life of which that one constituent is indispensable. When crop response to the quantity of an essential nutrient present in soil or added to it increases in direct proportion, it can be expressed by the following linear equation:

$$y = a + mx \quad (1)$$

where y is the crop yield, x is the quantity of nutrient added, a is the intercept, and m is the slope. Eq. 1 applies to low soil fertility conditions and for nutrient uptake. In such cases, the value of a , the intercept, is equivalent to the plant-available quantity of nutrient in soil.

However, as the quantity of a nutrient increases, the unit increment in crop yield becomes smaller, and eventually, the crop yield reaches a maximum value. The crop response curve is then represented by the Mitscherlich equation:^[2]

$$y = A(1 - e^{-Cx_t})$$

or

$$y = A(1 - e^{-C(x+b)}) \quad (2)$$

where x_t or $x + b$ is the total nutrient, b is the plant-available quantity of nutrient in soil (and seed, considered if present in significant quantity), A is the maximum yield attainable when $x + b$ is present in sufficient quantity, and C is the efficiency factor.

When quantity of a nutrient present in, as well as added to, soil is in excess of crop requirements, the nutrient becomes toxic to plants or other factors become yield limiting, and then the crop yield response curve obeys polynomial equations such as the quadratic equation as follows:

$$y = a_1 + b_1x + c_1x^2 \quad (3)$$

where a_1 , b_1 , and c_1 are constants. The maximum yield is given by the value of $-b_1/2c_1$. When y is expressed as the nutrient uptake, a_1 estimates the quantity of available nutrient in soil.

Because maximum yield, A in Eq. 2 and $-b_1/2c_1$ in Eq. 3, varies across crops, soils, seasons, and years, it is usually preferable to express plant productivity as relative yield in a field experiment. The relative yield at a given nutrient supply is $100 \times y_n/A$ from Eq. 2 and $100 \times y_n/(-b_1/2c_1)$ from Eq. 3, where y_n is the crop yield at a given nutrient supply in soil.

This biological assessment of soil fertility evaluation is shown in Fig. 1.

Although this biological assessment in the field is the most appropriate system for soil fertility evaluation, it is expensive and time-consuming and subject to the limitations and constraints imposed on crop growth because of other factors such as pests, diseases, water stress, and spatial variability. It is primarily used for benchmarking other soil fertility evaluation systems such as plant analysis and tissue testing, soil testing, and remote sensing.

PLANT ANALYSIS

When nutrient deficiency is severe enough, plants exhibit visual symptoms,^[3] and this provides a rapid but qualitative

Fig. 1 Crop yield response curve with quantities of a nutrient added in soil (and seed, if contributing significant quantity); the quantity in soil is estimated from the values of a in Eq. 1, b in Eq. 2, and a_1 in Eq. 3.

assessment of soil fertility. Conversely, nutrient toxicity in the presence of excess nutrients and heavy metals in soil can be readily assessed from visual symptoms on plants in the field.^[3] However, it is often too late to take corrective measures to avert the decline in crop yields. Other limitations include disease, undefined symptoms, environmental factors, and multinutritional disorders.

Because critical nutrient concentration range ($\approx 90\%$ maximum yield) in plants at which crop yield is affected is relatively narrow, plant analysis for critical nutrient concentration has been used to evaluate soil fertility and recommend nutrient applications to correct nutrient deficiency.^[3]

The further application of plant analysis for critical nutrient concentration is in tissue testing of a crop growing in the field. This involves a rapid analysis of a nutrient, a form of the nutrient such as nitrate for nitrogen (N), enzyme activity such as nitrate reductase activity for nitrate, ribonuclease activity for zinc, and greenness index for chlorophyll associated with critical N concentration in the leaf. It usually provides only a qualitative or semiquantitative assessment of soil fertility because the critical concentration differs among crop cultivars, crop types, incidence of disease, time of sampling, nature of nutrient interactions, water supply, temperature, dry matter yield level, physiological maturity of the leaf or plant part sampled, and other undefined factors.

The balance of nutrients within a plant is often more important than the concentration of any individual nutrient. The diagnosis and recommendation integrated system (DRIS) focuses on nutrient balance as an alternative to the critical nutrient concentration range approach to plant

analysis interpretation. One advantage of the DRIS is that nutrient ratios in plants tend to be less variable throughout the growing season than individual nutrient concentrations, especially for mobile nutrients such as N, phosphorus (P), and sulfur, but there is no universal benchmark nutrient ratio for plants.^[4]

SOIL TESTING

Soil testing provides a rapid chemical and/or biological analysis to assess the quantity of plant-available nutrients in soil and, hence, for the evaluation of soil fertility.^[4-6] This is usually done by analyzing an extract of the soil obtained by adding water, chemical extractants, ion-exchange resin and membranes, and electro-ultrafiltration. Short-term incubation, especially for assessing N mineralization, fungal growth such as *Aspergillus niger*, or even short-term plant growth in the greenhouse, is employed as biological methods for soil testing. However, biological methods are time-consuming and are rarely used in soil testing except for short-term anaerobic N mineralization.^[4]

Unfortunately, most values of plant-available nutrients are expressed on a soil's mass basis rather than on the volume basis; the latter requires soil's bulk density and depth of sampling. Furthermore, for most plant-available nutrients, soil from only the top 10-cm or 30-cm depth is sampled although crop roots access nutrients and water from much deeper layers, often deeper than 100 cm in many soils.

SOIL TEST-CROP RESPONSE CORRELATION

Soil test values are used for evaluating soil fertility of a group of soils based on correlation with crop response such as dry matter yield, crop yields, nutrient yield, or nutrient concentration. It is essential that the soil tests be calibrated against crop response to applied nutrients in field experiments conducted over a wide range of soils, crops, and climate. A properly calibrated soil test correctly identifies the degree of deficiency or sufficiency of a nutrient. This is shown in Fig. 2.

Most soil tests are based on theoretical consideration of some aspects of plant nutrient availability (i.e., intensity, quantity, buffer power, and diffusion of nutrients in soil). Isotopic dilution techniques are used to label the plant-available nutrient in the soil, such as P in greenhouse or field, and then to trace its availability through crops, thus avoiding the artifact effects of soil extractants.^[7] In some soil test-crop response correlation procedures, soils are grouped according to clay content, cation exchange capacity, or soil pH, and separate calibrations are established for each group of soils. In fact, the fertility capability soil classification system groups soils according to surface soil texture, subsoil texture, and 15 other soil characteristics.^[8]

Fig. 2 A diagrammatic representation of soil test-crop response correlation to evaluate soil fertility of a group of soils. In the deficient range, soil fertility status is further classified as very low (<50% relative yield), low (50–75% relative yield), medium (75–90% relative yield), and high (>90% relative yield). Toxic range is of special interest for environmental considerations of soil fertility.

SPECTRAL SENSING AND SITE-SPECIFIC SOIL FERTILITY EVALUATION

Soil fertility variability in conventional soil testing, which aims at obtaining an average value for a field or experimental site, is not evaluated to make site-specific management decisions. The two outstanding benefits of site-specific soil fertility evaluations are 1) increased economic efficiency of nutrient application, i.e., maximum profits; and 2) consequent reduced environmental nutrient pollution. Spectral sensing techniques (physical soil testing) such as static and portable near- and mid-infrared, gamma ray, and satellites using hyperspectral sensors^[9] are increasingly being used to map soil fertility for multiple nutrients and crop yields at <1 m² scale to >1 km² scale, while using precision technologies for site-specific nutrient applications.

ENVIRONMENTAL IMPACT

Usually, maximum economic yield is obtained with soil nutrient supply just enough for achieving about 90–95% of relative yield when nutrients are fully taken up by plants. In crops when quality of the product attracts a premium such as protein concentration of wheat >11.5% protein, N supply at the higher level of sufficiency and luxury range is economically preferred. Yet high soil nitrate-N fertility may lead to excess of nitrate-N in soil and, consequently, to denitrification (greenhouse effect) and leaching. Excess nitrate-N in surface water bodies causes algal blooms and in drinking water causes methemoglobinemia in infants. Also, adverse environmental and health impacts occur when soil nutrient fertility is in toxic range (Fig. 2), especially for heavy metals, because of human consumption of product or on ecosystems.

PERSPECTIVES

Soil fertility evaluation has evolved in the last two centuries, from a major concern for enhancing crop production to that of maintaining environmental integrity. With increasing population, crop production will be the main objective of managing the soil fertility. However, with the advances in multielement extractants and analysis and remote sensing and precision technologies for site-specific soil fertility evaluation, it is possible to meet the twin goals of economic optimum yields and minimal environmental pollution. By managing soil fertility this way, sustainable use of land, water, and nutrients is also ensured, resulting in enhanced soil and water quality for the existing and future generations. In spite of the advances in sensor and analytical technologies, however, the challenge lies ahead in developing soil nutrient tests that closely mimic nutrient uptake by a crop.

CONCLUSION

Significant progress has been made in soil fertility evaluation systems in last decades because of valuable contributions made by ecologists and geographers, besides the continuing interest from agronomists and soil scientists. Consequently, a broad spectrum of technologies is being applied to soil fertility evaluation for sustainable natural resource management, food and fiber production, and ecologically sustainable practices for the benefit of both rural and urban communities. Further refinements in soil fertility evaluation systems would come from the integrative use of both classical and spectral technologies and spatial and computational capacities for their appropriate applications to ecosystems and landscapes.

Fertility: Low Input and Traditional Maintenance Methods

Miguel Altieri

University of California—Berkeley, Berkeley, California, U.S.A.*

Abstract

Throughout the world, more and more farmers are learning that the combination of reduced tillage, cover crops, and better rotations can have a dramatic effect on their soil and the health of crops. They found that, by combining practices, they were able to reduce pest damage, improve soil tilth, vastly reduce runoff and erosion, increase soil organic matter, and produce better crop growth.

INTRODUCTION

There are thousands of farmers throughout the world (mostly organic farmers and resource-poor farmers) who, due to economic constraints or environmental reasons, cannot or do not want to use chemical fertilizers to enhance or maintain soil fertility.^[1] These farmers who can neither afford nor rely on a regular supply of inorganic fertilizers must find alternative sources of nutrients. These sources are often cheaper, more efficient than inorganic compounds and their use focuses on recycling of nutrients rather than on supplying nutrients on a regular basis.^[2] The techniques that these farmers use to maintain soil fertility and to improve biological, chemical, and physical soil properties tend to enhance organic matter content and increase the efficiency of nutrient use by closing the nutrient cycles (by returning exported nutrients to cropland) and by minimizing nutrient loss from the agroecosystem.^[3]

PRINCIPLES OF LOW-INPUT SOIL FERTILITY MANAGEMENT

Although many farmers have developed alternative fertilizing techniques through trial and error, research showed that there are several agroecological principles underlying such low-input methods of maintaining soil fertility.^[4,5] Such principles can be summarized as follows.

Securing Arable Soil Conditions for Plant Growth

In order to grow healthy and productive plants, farmers must create and/or maintain the following soil conditions:^[6] 1) timely availability of water, air, and nutrients in balanced and buffered quantities; 2) soil structure that enhances root growth, exchange of gaseous elements, water availability, and storage capacity; 3) soil temperature that

enhances soil biology and plant growth; 4) absence of toxic elements such as pesticide residues; 5) increased addition of organic residues by using varied sources of organic materials.

Optimizing Nutrient Availability and Cycling

Nutrient availability depends greatly on the general soil condition, soil life, and organic matter content. However, deliberate attention must also be given to providing the nutrients required for plant growth. There is a constant flow of nutrients through the farm. Some of the nutrients are lost or exported, e.g., by export of products, erosion, leaching, and volatilization. These nutrients have to be replaced. Nutrient losses can be limited by:^[7] 1) recycling organic wastes, e.g., manure, night soil, and crop residues by returning them to the field, either directly or treated (composted, fermented, etc.); 2) handling organic fertilizers in such a way that nutrients are not leached by excessive rain or volatilized by high temperature or solar radiation; 3) reducing runoff and soil erosion, which removes nutrients and organic matter; 4) reducing burning of vegetation when farming is intensified, as this leads to losses of organic matter; 5) reducing leaching by maintaining a high humus content in the soil and soil cover and intercropping plant species with different rooting depths; and 6) pumping up partly leached nutrients from deeper soil layers and bringing them back to the topsoil by using litter from trees or other deep-rooting plants.

Clearly, nutrient export from the farm to the market cannot be completely avoided nor can all nutrient losses resulting from erosion and leaching. However, soil cover and efficient organic management can minimize losses to acceptable levels. In fact, nutrients can be captured on the farm by:^[8] 1) fixing nitrogen by microorganisms living in symbiosis with leguminous trees, shrubs, or cover crops; 2) harvesting nutrients by capturing wind or water sediments

from outside the farm; this can be done with special soil conservation practices; and 3) integrating livestock into the farming system.

TECHNIQUES FOR SUSTAINABLE SOIL FERTILITY MANAGEMENT

The above principles are universal in nature but when applied by different farmers under a diversity of environmental and socioeconomic conditions, principles take various technical forms which can be grouped as follows.^[9]

Soil Conservation

The most effective way to improve the productivity of small, resource-poor farmers is to conserve and utilize the resources that they already possess. Soil conservation thus aims to maintain soil fertility by preserving soil structure, organic matter, and nutrients. These practices include techniques that decrease rates of leaching, erosion, and organic matter destruction. Also important are methods that capture and conserve water, especially in low-rainfall areas, for water and soil fertility act synergistically on crop production.^[3]

Conservation techniques are often advantageous because they require little outlay of cash and they can usually be undertaken during the fallow season, when farmers have less work. As a result, they do not put the farmer in debt risk and they do not interrupt or interfere with traditional work schedules. These techniques include the use of windbreaks, terraces, and deep-rooted plants. Windbreaks are usually composed of tree hedgerows planted at regular intervals in a crop field. They reduce erosion by reducing wind velocity. Terraces can be used to prevent soil erosion on cultivated steep lands. Although large-scale terracing programs may be expensive and require much labor, there are several techniques for low-resources terrace building, in which the terraces actually build themselves.^[10] Deep-rooted plants, such as perennial shrubs and trees, can be used to recycle nutrients that have leached to deeper layers in the subsoil, beyond the reach of the roots of most crop species. This strategy is particularly important in certain forms of agroforestry such as alley farming.^[11]

Nutrient Recycling

The nutrients that are removed from agricultural fields as crops eventually become wastes and thus can be reused in the field. Some wastes, such as manure, can be used directly on cropland, but most organic materials must first be “prepared” before they are used as a fertilizer. The variety of materials that have been used to maintain soil fertility include animal wastes, bones,

blood, seaweed, seashells, peat, ashes, sawdust, leaves, sewage, sludge, and so on.^[2]

In temperate regions, one of the most common recycling practices is the use of “mixed” farming, where livestock or chickens are the chief product of the farm. On these farms, grains and hay are grown and fed to the livestock. Their manure is used to fertilize the soil. Legumes are grown in rotation with grain crops in order to resupply the soil with nitrogen. Opportunities are endless, but the main approaches include the following.

Cover crops and green manures

Some crops are grown solely for the purpose of enhancing soil fertility. These crops are not harvested, but rather they are plowed into the soil, while they are still growing, which is why they are referred to as green manures. Typically, green manures or cover crops are grown in rotation or as “improved fallow” and are mixed into the soil before seeding the subsequent crop, allowing enough time for the decomposition of residues and the mineralization of nutrients. Green manures serve many different purposes in soil fertility. They can improve the soil physical structure by adding organic matter. They can be used to prevent erosion, as when they are used as a fallow season cover crop. They can improve soil nutrient status when they are used as “nutrient pumps” to recycle nutrients that have leached to deeper horizons.^[12] When a legume is used as a green manure crop, large amounts of soil nitrogen may be added.

One of the most remarkable cover crops is the velvet-bean (*Mucuna pruriens*). This has been widely promoted as part of the work of World Neighbors in Central America, though its effectiveness is attested by its spontaneous spread from village to village without outside intervention. Establishing *Mucuna* requires very little investment in labor. It grows rapidly, is palatable to animals and people, fixes large amounts of nitrogen, and can produce as much as 60 ton/ha of organic matter. It can grow on most soils, and its spreading habit suppresses weed growth. Incorporating such green manures into cropping systems can increase yields substantially. Honduran farmers are able to harvest some 2.5–3.2 ton/ha of maize when grown after velvetbean. This compares with an average for the country of just 0.6 ton/ha.^[13]

Azolla and anabaena

Blue-green algae are another important source of nitrogen, the most widely exploited being the alga *Anabaena azollae* which fixes atmospheric nitrogen while living in cavities in the leaves of a small fern, *Azolla*, which grows in the water of rice fields in both tropical and temperate regions. *Azolla* quickly covers the water surface in the ricefield but does not interfere with the normal cultivation of the rice crop.

Very high nitrogen production is possible following *Azolla* inoculation in rice fields. In the Philippines, 57 tons of fresh weight *Azolla* can be harvested after 100 days yielding more than 120 kg/ha of nitrogen. Over the whole year, *Azolla* can fix more than 400 kg N/ha, a rate in excess of most tropical and subtropical legumes. This nitrogen is only available to the rice crop after *Azolla* has decomposed and so exploitation consists of incorporating the ferns into the soil while wet as a green manure or removing them for drying and then reapplying them to the ricefields. The results of at least 1500 studies in China, Philippines, Vietnam, India, Thailand, and the United States have shown that when *Azolla* is grown in paddy fields, rice yields increase by on average 700 kg/ha, with a range of 400–1500 kg/ha.^[11]

Mulches

Soil fertility can often be enhanced simply by covering the soil's surface with a layer of organic material (mainly straw), a process that is known as mulching. In the humid tropics, where cultivation of any sort is often deleterious to soil fertility and crop productivity, mulching is a highly effective method to maintain soil health. Mulches are particularly useful in preventing soil damage because they reduce the destructive effect of raindrop impact on soil aggregation and prevent soil erosion. Mulches also improve soil water status by increasing infiltration rates. Mulches also stimulate the growth of soil biota.^[9]

Agroforestry and intercropping

There is a huge diversity of agroforestry systems throughout the world, in which the incorporation of bushes and trees result in many benefits. Trees with nitrogen-fixing capacity have beneficial effects on plants growing beneath them. In many arid parts of Africa, millet is planted under *Acacia albida* trees. The acacias, which conveniently drop their leaves at the start of the growing season, provide nutrients for the growing crop; millet yields under the tree's canopy are 56–64% higher than yields obtained away from the tree.^[14] Most positive effects of trees are the result of the fixed nitrogen, but significant quantities of N can also be supplied in the leaf litter or from deliberate pruning. In Africa, leguminous shrubs (*Leucaena*) are grown as hedgerows 2–4 m apart, and their prunings added to crops grown in the alleys. This proved a remarkably efficient agroforestry technique to stabilize maize yields at about 2 ton/ha without the use of fertilizers.^[15]

Trees also improve the microclimate by acting as wind-breaks, by improving the water-holding capacity of the soil, and by acting as shade trees for livestock—so focusing the deposition of manure.^[16]

Intercropping, the process of growing more than one crop simultaneously in the same plot, is used throughout the world and has many advantages over monoculture, including a more efficient use of space and nutrients, higher total yields, and less vulnerability to crop failure due to pests.^[17] As in the case of maize–bean polycultures, legumes can be used in the intercrop to add nitrogen and thereby reduce competition between the intercropped species. In fact, bean-fixed N is made directly available to the maize through mycorrhizal fungi connections between root systems. Intercropping also helps prevent erosion and soil surface damage (i.e., degradation of surface pores) by keeping the soil covered. Due to these and other effects, polycultures generally overyield corresponding monocultures.^[18]

Integration of livestock

Livestock are a critical component of sustainable agricultural systems. The nutrient value of manures largely depends on how it is handled, stored, and applied. Losses of nitrogen tend to be highest when liquid systems of storage are used and when the manure is broadcast without incorporation. Livestock manures from cattle, pigs, and chickens are important, as they positively affect soil structure and water retention, and benefit soil organisms. Manure itself is an excellent fertilizer, and soils usually require 5–20 ton/ha of fresh manure to remain in continuous productivity.^[19]

It is becoming more common for small farmers to keep their animals permanently penned in zero-grazing or stall-feeding units rather than permit livestock to graze freely. In many rural areas, zero-grazing units are a central part of efforts to improve soil and water conservation. Fodder grown on the farm in the form of improved grasses, tree fodder, and the residues of cultivated crops are cut and carried to the animals. Because of the proximity to the crops, manures can be returned directly to the land, so improving nutrient supply and soil structure.^[20]

Reduced tillage

The use of reduced tillage or no till systems can maintain or enhance soil organic matter more than the conventional moldboard plow and disk system. The decreased soil disturbance under reduced tillage slows the rate of organic matter decomposition and helps maintain a soil structure that allows rainfall to infiltrate rapidly. Leaving residue on the surface encourages the development of earthworm populations, which also improves soil structure. Compared with conventional tillage, soil erosion is greatly reduced under minimum tillage systems, which helps keep the organic matter and rich topsoil in place. The only drawback of these systems is their high dependence on herbicides.

Composting

Organic wastes can also be concentrated through the process of composting, in which microorganisms attack the waste before it is used as fertilizer. There are many methods of composting, each combining the use of animal manures, green material, and household wastes in different ways and proportions. The materials are heaped or placed in a pit in such a fashion that anaerobic decomposition occurs. Harmful substances and toxic products of metabolism are broken down, while pathogens and the seeds and roots of weeds are destroyed by the heat generated within the compost heap. Compost created by a variety of methods has proven to be an effective fertilizer in many agricultural settings.

Inoculating the soil with microorganisms

Soil microbes play many beneficial roles in maintaining soil fertility. In some situations, however, these beneficial microbes might be present in very low numbers. In such situations, the soil can be “inoculated” with beneficial microorganisms thus enhancing crop productivity. These introductions may be done with any species of microbe that is known to benefit plant productivity. Those species that fix nitrogen, enhance phosphorus availability, increase mineralization of soil organic matter, or prevent diseases have attracted the attention of researchers. There are many studies that have examined the use of improved strains of the nitrogen-fixing bacterium *Rhizobium*, the nitrogen-fixing soil bacteria *Azotobacter* and *Azospirillum*, and Mycorrhizal fungi that enhance plant phosphorus nutrition.^[21]

INTEGRATED APPROACHES TO SOIL FERTILITY MAINTENANCE

As discussed earlier, there are many options for making soils more healthy and fertile. Combining the various options is challenging but usually implies the following.^[7]

1. Using rotations that utilize grass, legume, or a combination of grass and legume sod crops: or crops with large amounts of residue as important parts of the system.
2. Using of cover crops when soils would otherwise be bare to add organic matter, capture residual plant nutrients, and reduce erosion. Cover crops also help maintain soil organic matter in resource-scarce regions that lack possible substitutes to using crop residues for fuel or building materials.
3. Leaving residues from annual crops in the field or, if they were removed for use as bedding for animal, returning them to the soil as manure or compost.

4. Raising animals or having access to animal wastes from nearby farms gives farmers wider choices of economically sound rotations. Rotations that include perennial forages make hay or pasture available for use by dairy and beef cows, sheep, and goats. In addition, on mixed crop-and-livestock farms, animal manures can be applied on cropland. It is easier to maintain organic material on a diversified crop-and-livestock farm, where sod crops are fed to animal and manures returned to the soil. However, growing crops with high quantities of residues plus frequent use of green manures and composts from vegetable residues helps maintain soil organic matter even without animals.

Throughout the world, more and more farmers are learning that the combination of reduced tillage, cover crops, and better rotations can have a dramatic effect on their soil and the health of crops. They found that, by combining practices, they were able to reduce pest damage, improve soil tilth, vastly reduce runoff and erosion, increase soil organic matter, and produce better crop growth.^[22] Among resource-poor farmers in developing countries, adoption of sustainable soil fertility management practices can have important impacts on crop yields. An analysis of 208 agroecological projects showed clear increases in food production over 29 million hectares, with nearly 9 million households benefiting.^[11] In North America and Europe, organic farmers who adopt low-input soil fertility practices typically obtain yields 6–11% lower than conventional farmers who rely on chemical fertilizers. Such lower yields are, however, offset by the economic and environmental performance of organic agriculture.^[2]

Abstract

Sustainable use and management of soil quality in Huang–Huai–Hai plain are critical to China's food security because it produces almost 35% of China's maize and 70% of wheat. Historically, soil quality of cropland was low due to salinization by topographic, hydrologic, and hydrogeologic conditions. Thus, a series of reclamation techniques for salt-affected soils were implemented. The widespread adoption of recommended techniques of soil reclamation improved soil quality. Consequently, soil organic carbon (SOC) was improved between the 1980s and 2010s, and SOC concentration is 12.34 g kg⁻¹ in Quzhou and 6.0–13.4 g kg⁻¹ in Yucheng. However, sustainable improvement in soil quality can also face major challenges of groundwater depletion, greenhouse gas emissions, excessive agricultural intensification, and the potential adverse effects on salt balance affected by increase in temperature. Strategies such as sustainable intensification, increase in SOC, and decrease in salt content must be the research priority for improving soil quality.

INTRODUCTION

Soil quality is the key factor affecting crop production and the quantity of input including chemical fertilizers, pesticides, groundwater, and the labor. Thus, soil quality is the basis of cropland production and a critical indicator of the environment.^[1] However, soil quality is affected by many factors such as climate, topography, parent materials, land use change, and intensification.^[2] While soil quality differs widely over time and space, management is critical to improving soil quality at plot, farm, region, and even global level.^[3–5] Therefore, management and sustainable use of soil quality are the research priority.

Soil quality is high in the United States that supports high crop production with less input;^[6] on the contrary, high crop production in China has been realized by higher input because of low inherent soil quality.^[7] Consequently, farmers in China have to apply high rates of nitrogen (N), phosphorus (P), and potassium to sustain high yields. Therefore, China is considered the global hot spot to ensure food security while reducing greenhouse gas (GHG) emissions by agricultural intensification.^[8] China, India, and the United States together account for 64–66% use of N and P. Furthermore, rice, wheat, and maize are alone responsible for 58–60% use of N and P.^[8] Thus, achieving food security in contemporary China faces major challenges including increase in crop production by sustainable systems of improving soil quality of cropland while reducing the negative environmental effects. Therefore, sustainable

management of soil quality of cropland helps China not only to ensure its food security but also to reduce GHG emissions. This entry aimed at considering the Huang–Huai–Hai (HHH) plain as an example to demonstrate the techniques of sustainable management of soil quality in China.

SOIL QUALITY MANAGEMENT IN THE HHH PLAIN

The HHH plain is formed by alluvial sediments deposited by the following three rivers: Huang He or Yellow, Huai, and Hai rivers. It is the largest plain (~350,000 km²) in China consisting of five provinces, i.e., Hebei, Henan, Shandong, Anhui, Jiangsu, and two municipalities i.e., Beijing and Tianjin. It is home to 35% of China's total population.^[5]

The region has a semihumid climate with an annual precipitation of 500–900 mm. About 60–75% of the annual precipitation is concentrated in summer monsoon period, and the other seasons either are dry or receive only a little rainfall. Topographic, hydrologic, and hydrogeologic conditions make the soils of this region prone to salinization. In addition, the alluvial plain is relatively flat in topography and has impeded surface drainage. Thus, climate, coupled with shallow groundwater of high salinity, leads to the widespread salinization in the HHH plain.

The entire HHH plain is divided into three subregions on the basis of soil and watershed flow, groundwater distribution, temperature, and precipitation. Subregion I comprises

Fig. 1 Change in crop production during 1985–2010.

the piedmont plain of Taihang and Yan Mountains. Principal soils of the subregion I include argillic fluvo-udic and fluvo-aquic Inceptisols. The groundwater table is deep, and salt concentration is low ($<0.1\%$ in soil profile); subregion II comprises the flood and coastal plains of Huang He and Hai rivers. Principal soil types of this region are light, medium, and heavy saline fluvo-aquic Inceptisols. This subregion has saline phreatic water reserves ($2\text{--}10\text{ g L}^{-1}$), which may exacerbate the risks of salinization,^[9] subregion III comprises the flood plains of Huang He and Huai rivers. Principal soil types of this region are yellow fluvo-aquic and light saline fluvo-aquic Inceptisols, and relatively high rainfall leaches salts into the subsoil. Prior to the 1980s, there were 2.33 million hectares (Mha) of salt-affected soils and an additional 2.67 Mha of soils with high risks of salinization.^[9]

Soils of the HHH region have low inherent quality affected by the factors such as salinization, drought, and waterlogging due to the climate, topographic, hydrologic, and hydrogeologic conditions of this region. Therefore, the region suffers from both frequent droughts and waterlogging, and the soil salinization was a historically widespread problem.

Therefore, a series of reclamation techniques of salt-affected soils were implemented. Reclamation techniques included regionalization for comprehensive evaluation and monitoring, predicting, and regulating the regional water and salt movement. The widespread adoption of

recommended techniques of reclamation coupled with the soil quality improvement practices decreased salt concentration in soils and enhanced soil organic carbon (SOC) concentration across the HHH region.

Thus, HHH plain is an important region of arable land use in China with double-cropping system of winter wheat (*Triticum aestivum*) and summer maize (*Zea mays*). The HHH produces almost 35% of China's maize and 70% of wheat (Fig. 1),^[5] and the average yield of grain crops (kg ha^{-1}) has increased from 1582 to 5860 for wheat (Fig. 2) and 4492 to 5610 for maize (Fig. 3) between 1985 and 2010. The yields of HHH region are 1.25 and 1.07 times the China's national average yields of wheat and maize, respectively. However, agricultural intensification has also increased SOC concentration between the 1980s and 2010s, which was 12.34 g kg^{-1} in Quzhou, $6.0\text{--}13.4\text{ g kg}^{-1}$ in Yucheng, and 10.4 g kg^{-1} in Huantai.^[3]

CHALLENGES FOR SUSTAINABLE MANAGEMENT OF SOIL QUALITY IN THE HHH PLAIN

Managing soil quality of cropland is facing serve challenges in the HHH region from groundwater depletion, climate change, excessive agricultural intensification, and the scarcity of data on soil quality. All these factors impact soil quality and sustainable use. Thus, the management of soil quality should be done according to the changing trends in soil quality and the potential adverse effects.

The highest risks of adverse changes in soil quality come from the widespread groundwater depletion for both deep and shallow aquifers. The HHH accounts for 16% of the China's national average arable land but has access to only 7.6% of the China's national average renewable water resources compared with the highly endowed southern region.^[10,11] During the 1970s, farmers installed irrigation wells at 5–10 m depth.^[12,13] During the 2010s, the irrigation wells are installed at 300–400 m depth in eastern parts of the HHH, and many farmers have abandoned winter wheat in the northern parts of the HHH because of insufficient groundwater. Thus, the northern parts of the HHH are

Fig. 2 Change in wheat yield during 1985–2011.

Fig. 3 Change in corn yield during 1985–2011.

no longer suitable for cultivation because the aquifer would be exhausted within 40 years.^[11] The seasonal and interannual deficit of groundwater due to intensive cropping of wheat and maize perturbs the hydrologic balance in the HHH. It is the excessive pumping of groundwater for intensive wheat production that causes a rapid decline in groundwater year after year.
